All human measurement, unless guided by explicit points of reference in a defined context (which is what panel training hopes to achieve), is relative. One does not know, for example, whether an 18 °C day is cool or warm unless they know the season and the location. The situation is no different with consumer assessments of liking – they are always comparative. In the relatively rare situation, for example, that a single product was rated for liking, one would expect that the point of comparison was the consumer's prior experiences with that class of product (Walter and Boakes, 2009). In the more usual situation in which multiple products are compared within the same evaluation session, the products are compared relative to one another. One consequence of the influence of context in ratings is that a given product can be given a low or a high liking rating entirely as a function of what other products are in the evaluation (Schifferstein, 1995). Recent work suggests that the effects may be more subtle than simply being within a high or low context, as biased responses can also occur as a function of similarity to other products within the set (Hayes *et al.*, 2011a,b).

It is crucial to understand the implications of context effects if consumer data are not to be misused. Many companies have in the past, and to a lesser extent still today, relied on a fixed acceptability criterion. For example, on the standard 9-point hedonic scale (9PS) (see below), a mean rating of 7 in consumer testing may be required to launch the product. Because any given number on the rating scale can only be really understood in relation to the ratings given to other products, there is no validity to adopting such a value. Ironically, dogmatic reliance on such cutoff values is a key reason why there is resistance in industry to adopting new approaches to measurement.

Hedonic Ranking and Rating

Simple questions of preference – do I like version 1 or version 2 of a product most? – can be answered easily using paired preference (2 samples) or ranking (>2 samples) procedures. Like ranking based on intensity (see Section Scaling), these provide nonparametric ordinal data, which do not allow any inferences about the relative magnitude of liking, that is, degree of difference between the samples.

Hedonic scaling has adopted similar approaches to that of intensity scaling, using both multiple category and line (VAS) scales, the latter with endpoint descriptors (e.g., 'dislike very much'; 'like very much') only. The oldest and still most popular method of determining degree of liking is the 9PS developed by the well-known psychologist L.L. Thurstone, in the 1950s, for the use by the US Army at the Quartermaster Food and Container Institute in Chicago (Jones *et al.*, 1955). The scale, shown in **Figure 3(a)**, uses nine labeled categories. The developmental work by Thurstone and colleagues aimed to find labels that were judged as psychologically equidistant from one another. Hence, the degree of difference (or interval) between like moderately and like slightly is meant to be approximately the same as the distance between neither like nor dislike and like slightly. As noted earlier in relation to intensity scales, the absence of valid zero point in interval scales means that the scale does not have ratio properties, so one cannot conclude that a product that receives a rating of 8 (like very much) is twice as liked as one that receives a rating of 4 (slightly dislike). The fact of this scale's widespread and long-standing use in industry has generated considerable inertia in terms of resistance to adopting other scales that perhaps have advantages (Lim, 2011).

Most recently, scales that seek to emulate the apparent ratio properties of the labeled magnitude scale (LMS) of intensity (see Section Scaling) have been developed (Lim *et al.*, 2009; Schutz and Cardello, 2001). In principal, such ratio scales (**Figure 3(c)**) should allow statements about the relative degree of liking. Moreover, the fact that the data appear to be normally distributed removes objections about the use of parametric statistics for analysis. Lim *et al.* (2009) compared the labeled hedonic scale (LHS) with the 9PS, showing that for a range of products, the LHS data were normally distributed, whereas those of the 9PS were not. With products that were highly liked, the 9PS showed ceiling effects, with responses compressed at the upper scale end. When equated for scale

length, the LHS also gave a greater range of ratings for the same set of products, hence potentially improving hedonic discriminability. However, the LHS shares with its LMS cousin potential drawbacks in terms of ease of use. The first of these is the need to explain to consumers the meaning of the end labels most liked/disliked sensation imaginable and to firmly locate the context as all sensations and not just the category (e.g., sweet foods) being evaluated. A related issue is the need to include some form of practice using nonfood examples (e.g., 'most enjoyable film'), allowing both a check of the consumer's understanding of the scale and a measure that will allow a check against idiosyncratic scale usage. Whether or not these potential drawbacks will influence the uptake of the scale is still to be determined.

Special Populations

The rapid growth of the market for food aimed specifically at children has necessitated the development of hedonic methods that can be employed when the consumer has limited linguistic or cognitive skills. Even at a very young age, children's food preferences and choices are greatly influenced by what their peers eat (Birch, 1980), meaning that parental assessments of children's preferences are unlikely to be accurate once the child reaches (pre)school. There have been two general approaches to this problem (Chen *et al.*, 1996; Popper and Kroll, 2005). The first of these is to use ranking or rating procedures modified to fit the presumed cognitive sophistication of the child. This is usually accompanied by labels such as best, worst (ranking), or various versions of easily understandable hedonic terms such as really/super good, good, bad, 'OK,' and really/super bad attached to category scales. A presumption is that the younger the child, the fewer the categories that should be employed. Very young children are sometimes tested by making the procedures into a game, for example, by placing a ball into a 'bad' bucket if a sample is disliked or into a 'good' bucket if it is liked (e.g., Turnbull and Matisoo-Smith, 2002). An alternative approach has been to use emotional expressions as indicators of liking. This can mean either interpreting facial expressions while infants are sampling foods (e.g., Forestell and Mennella, 2007) or using the so-called smiley face scales, in which degrees of liking are represented as categories by depictions of facial expressions. The benefits of this latter approach are that no language skills are required. However, there are concerns about the extent to which facial expression can adequately discriminate subtle degrees of liking.

Globalization of the food industry in recent decades has created a demand for understanding consumer preferences cross-culturally. However, understanding food choice/preference in other cultures presents particular problems. There are a variety of issues here, including not only language barriers but also trying to understand both appropriate food types and flavors and food-related values and consumption habits that are culturally determined (Prescott, 1998; Prescott *et al.*, 2002). In terms of methods, given the ubiquity of the 9PS in industrial applications in the US and some other Western countries, cross-cultural studies have focused to some extent on the development of equivalent versions for other cultures (Chung and Han, 2013; Curia *et al.*, 2001; Daroub *et al.*, 2010). The use of hedonic scales, particularly those with multiple labeled categories, presents complex issues of translation. For example, a scale label such as 'like extremely' may be entirely inappropriate when dealing with food generally or specific types of foods. The degree of discrimination implied by the use of nine distinct categories also cannot be assumed. Consideration, too, needs to be given to scale-usage issues. Expressions of emotion, especially in public settings, may be modified by cultural norms. Such norms may underlie findings that consumers in some Asian countries (China, Korea, Japan, and Thailand) used fewer categories of the 9PS in ratings of the same samples than Americans did, often avoiding the emotionally intense end categories (Yao *et al.*, 2003; Yeh *et al.*, 1998). Overall, the same problems that beset the use of hedonic scales as predictors of food choices (see Section Hedonic Measurement: Limitations and New Approaches) are magnified when attempting to interpret their output for other cultures. Likewise, even within a common language, cultural differences may confound interpretation of hedonic labels. A not unreasonable translation of 'actually quite good' in British English is in American English, 'totally awesome!'

Consumers as Discriminators

It is generally believed that consumers are relatively insensitive to the presence of, or variations in, sensory qualities, at least when compared with trained panelists. This is often true. As a result, there has been a reluctance to use consumers to undertake discrimination tests. This practice, however, relies on two assumptions that are increasingly being tested. The first of these is that high levels of sensitivity to product variations or differences is always better. However, consumers may be entirely appropriate to use when making judgments about what other consumer might perceive in products. In some cases, there may be situations in which the judgment of a trained panel overestimates the effect of, for example, ingredient changes or the presence of taints or off-flavors on consumer preferences – perhaps with economic consequences. An appreciation that this might be happening in the wine industry with rejection of wines that had become contaminated with cork taint (trichloranisol; TCA) by highly sensitive trained panels led to the development of a technique known as the consumer rejection threshold (cRT; also referred to as the rejection threshold) (Prescott *et al.*, 2005). This technique was developed using presentation of pairs of wines that are identical except for the addition of increasing amounts of TCA. The consumers were asked simply to taste both wines and indicate which they preferred. The cRT reflected the point (that is, the TCA concentration) at which the wine without the added TCA became consistently preferred. This study produced a threshold value that was considerably higher than the detection threshold values commonly provided by trained panels, the implication being that batches of wine were being unnecessarily rejected for low levels of TCA, even though the (untrained/typical) wine drinker would find them quite acceptable.

The second assumption in relation to the discriminative abilities of consumers that is currently being challenged is the idea that an emotional response – typically, liking or

disliking – is necessarily at odds with perceptual sensitivity. A technique known as the Authenticity Test has shown that when judgments are based firmly in a strong emotional context, they can be highly sensitive. The approach, first reported by Köster (Mojet and Koster, 1986) and since then replicated in a variety of contexts (Boutrolle *et al.*, 2009; Chae *et al.*, 2010; Frandsen *et al.*, 2007), has demonstrated that consumers are highly sensitive to product variations when they are first emotionally primed. In the Authenticity Test, as the name suggests, this takes the form of a story about products with which the consumers have high involvement. The story typically sets up a contrast between the 'authentic' version of their product (essentially a standard) and another version that the consumer is told is to be made from inferior materials, is a foreign import, or is made by nontraditional means. In fact, this comparison product is simply different in some way (e.g., another brand).

The explanation for the increased sensitivity of consumers in such contexts runs contrary to predominant beliefs about perception and effective decision making – namely, that it is optimized by a rational, disinterested, and above all nonemotional approach. In fact, there is increasing indication that an overly analytical approach may actually impair decision making (Halberstadt and Hooton, 2008). The explanation for the sensitivity of the Authenticity Test may also be linked to what social psychologists refer to as the Mood As Information hypothesis. It is suggested that people interpret their emotions and make judgments based on those interpretations (e.g., Schwarz and Clore, 1983). This allows misattribution of current emotion to the object of any decision making. In particular, negative emotions can act as threat signals that provoke cognitive effort to search for causes of the emotion. In the case of product evaluations, a mindset of Something's wrong with my product! What is it?! leads to increased attention to details. Hence, emotion produces increased analysis and consequently increased discriminatory power.

Hedonic Measurement: Limitations and New Approaches

Despite widespread consumer testing by the food industry over many decades, the results of such tests have had very limited success in predicting which few products, out of the thousands released each year, will succeed. Hedonic ratings of different prototypes coming out of product development will, if done properly, eliminate those versions whose flavors are either too weird to succeed or just too unpalatable. Beyond this, however, ratings on hedonic scales are seldom good predictors of food choices or consumption (Levy and Koster, 1999; Tuorila *et al.*, 2008). Partly, this is a function of food choice being influenced by very many external factors not captured by a scale of liking for a food's sensory properties. Moreover, there are a variety of factors to consider that make hedonic testing a complex process. This list includes (1) whether products should be tested branded or unbranded and should they be tested in a central location, in the home, or other situations in which the product is consumed; (2) can a judgment based on a 10-ml sample reflect one that might occur following the amount usually consumed; and (3) does testing several versions of a product, as is commonly done, produce the same response as when a consumer selects and consumes one version on which a decision is made. To some extent, in each of these examples, experimental control versus ecological validity is balanced but unfortunately, there is no simple way to address any of these issues. Or put it another way, the answer is 'it depends' as a function of the specific goals of the project.

One approach to address the limitations of simple judgments of likes and dislikes has been to tap into consumer emotions in more extensive and elaborate ways. It is recognized that foods are consumed not just for the sake of sensory pleasure but also for potentially quite complex effects on other emotions and attitudes. One clear example is the concept of 'comfort food.' Research into accessing a more complete picture of emotions associated with products is in its early days, and it is safe to say that there is, as yet, no standard way of doing this. Although emotion checklists and questionnaire have a long history in clinical psychology and psychiatry, such methods are of limited value in sensory evaluation because they are meant to tap into pathological, largely negative, emotions such as anxiety and depression. More recently, several new questionnaires have been developed that balance the positive and negative emotions. For example, the EsSense™ Profile employs 39 emotional terms and asks consumers to read a food name and then rate how the food makes them feel on a 5-point intensity scale (King and Meiselman, 2010). Studies using this scale have established that different patterns and intensity of emotions discriminate both between product names and the taste of those products, including between different versions of similar products – for example, milk and dark chocolate (Cardello *et al.*, 2012).

Consistent with psychological concepts of emotions as both expressive and physiological states, attempts have been made to automatically code for facial expressions and to measure indices of autonomic nervous system activity. One recent study combined both approaches in eliciting responses from both adults and children to the sight, smell, or taste of liked and disliked foods (de Wijk *et al.*, 2012). Initial responses to the sight of the disliked foods were evident in both skin conductance (a measure of sweat gland activity indicative of autonomic nervous system arousal) and increased frequency of facial expressions typically associated with sadness, disgust, and anger. Finger temperature was also lower for disliked foods. Beyond these findings, however, there was little indication that these measures (including heart rate) could be used to consistently differentiate liked from disliked foods. Interpreting physiological measures, in particular, is problematical. What exactly, for example, does arousal in response to a disliked food mean? What sort of arousal is it – the kind associated with anger or the kind associated with excitement? For example, a hot chili may cause the same physiological arousal in two individuals, one of whom enjoys this state, whereas the other does not.

All measures of emotions – whether mood checklist or physiological indices – carry the same general limitations. First, there is not yet an agreed on set of emotions or emotional terms for use in all circumstances. Second, emotions and their expressions are both well known to be context and culture dependent (see classic experiment by Schachter and Singer, 1962). Nevertheless, this may be a potentially fertile

area for further basic research, which may, in turn, lead to methods that can be applied in industry.

Yet another approach in the search for better predictors of consumer preferences has been to adopt measures that do not require explicit ratings by the consumer. Eye-movement tracking has been used to identify the visual features of products and their packaging that are important. For example, a recent study measured fixation time for the features for jam jars that varied in shape, texture, and label type (Piqueras-Fiszman *et al.*, 2013) and found that the presence of a picture on the label, together with certain textural features, was associated with an increased willingness to buy. Another method that shows potential is the implicit association test (IAT). Borrowed from social psychology, where this has been employed to study implicit attitudes, the IAT allows assessment of the congruency of particular semantic associations with product characteristics. This method, therefore, provides a way of uncovering product perceptions that are perhaps difficult to show using methods that require explicit statements of associations. The IAT is derived from findings that it takes longer to react to pairings of information (such as a brand and a label) that are incongruent than it does to congruent pairings. A study of mouthwashes using the IAT, for example, was able to show that one brand was primarily associated with the word 'powerful,' whereas a competitor was associated with the word 'gentle' (Parise and Spence, 2012). The IAT may prove useful studying, for instance, the compatibility of sensory characteristics with brands or brand images.

Consumer Profiling

Integrating sensory information derived from trained panels and consumer information statistically is a common approach to understanding sensory factors underlying preferences (see Section Combining Consumer and Descriptive Data). Nevertheless, there is growth in other approaches in which consumers alone directly assess a range of products. One method, identified with Moskowitz (e.g., Moskowitz, 2001), utilizes the consumer at the product development stage, asking them to evaluate product prototypes that vary systematically on one or more ingredient dimensions. This approach uses factorial designs such that the ingredients vary independently of one another. So, for example, a prototype orange juice might vary over four concentrations of sucrose, three concentrations of citric acid, and four concentrations of orange flavor, giving a total of 48 prototypes to evaluate. This allows for not only the impact of each of the variables (sugar, citric acid, and orange flavor) to be evaluated but also the interactions between them. The burden of evaluating a large number of samples can be relieved by using incomplete designs in which consumers evaluate overlapping subset of the total number of samples (ISO29842, 2011). An advantage of this method is that regression equations can be used to link the values of the variables to consumer acceptability so that linear or quadratic relationships can point the way toward levels of the ingredients that optimize acceptability (or whatever measure is used). Additionally, the method can be used to study variations in production processes or the impact of changing/substituting ingredients.

'Diagnostic' scales

It is possible to collect reformulation guidance directly from consumers using 'Just-about-right' (JAR) scaling. JAR scales are bipolar, with semantic anchors at each end; instead of rating intensity or liking, participants are asked to report how much of an attribute is relative to their personal hedonic ideal. The midpoint is labeled 'JAR,' indicating the attribute is at an appropriate level, whereas the ends are some variation on too strong or too weak. Most researchers use five categories (e.g., 'much too small,' 'somewhat too small,' 'JAR,' 'somewhat too big,' and 'much too big'), although it is also possible to use continuous line scales with suitable end anchors (Rothman and Parker, 2009). JAR scales are popular for optimization because they are very rapid and generate data that appear easy to interpret. For example, if a majority of participants indicate that a fruit punch sample is 'somewhat too sweet' or 'much too sweet,' it is clear that it should be reformulated by reducing the sugar level.

Nonetheless, several caveats need to be considered when using JAR scales. First, the word usage and concept alignment issues raised in Section Descriptive Profiling/Analysis also apply to JAR scales: naive consumers can probably assess and diagnose simple attributes like sweetness or sourness while they may struggle with more complex descriptors. For example, if the group indicates a product is too astringent, are they referring to drying sensations or puckering sensations? Just because a group of consumers can generate data for an attribute does not mean that they are all using the term in the same way or that the data are meaningful. Second, JAR scales may be influenced by desirability biases. Consumers may indicate that a cookie always needs more chocolate chips, even if adding more would result in a cookie that simply falls apart and is messy to eat and too chocolatey. Finally, consumer recommendations may negatively influence other, unmeasured attributes if the relevant ingredient contributes to multiple aspects of the flavor profile. For example, adding more oregano to the pizza may not only improve the aroma intensity but also add undesirable bitterness. Accordingly, caution and professional judgment are needed to successfully interpret JAR data: the consumer is not always right.

Sorting, napping, and check all that apply

One of the recognized limitations of profiling of products by trained, analytical panels is that trained assessors may describe products using attributes that are irrelevant for consumers and that have an uncertain relationship with product preferences. Unfortunately, although consumers frequently have the ability to distinguish between samples, they do so without being able to provide a clear semantic label to describe the qualitative differences between them. Additionally, consumers may use words to describe samples that have vague, or multiple, meanings that may be dependent on the individual's prior experience with the product class. In some cases, English may inherently lack sufficient precision to describe the differences, resulting in awkward questions like "Is it too spicy hot or too hot?" whereas a Spanish speaker might ask "Is it too *picante* or too *caliente*?"

A range of techniques known as perceptual mapping based on sorting of samples can provide easy-to-interpret visual maps of perceptual spaces and products or stimuli within

those spaces. These maps are based on perceived similarities between samples, as determined by the participants, and unlike trained descriptive panels, the participant is not constrained to a specific set of *a priori* descriptors. Rather, the consensus space is based solely on reducing the stress for some measure of similarity (or dissimilarity) across stimuli using multivariate statistical methods.

Early mapping approaches used multidimensional scaling (MDS) to reduce similarity/dissimilarity matrices built from pairwise comparisons using semantic differential scales into visual maps (e.g., Schiffman *et al.*, 1979, 1980). However, such approaches were extremely labor intensive as the number of comparisons required rises rapidly with the number of samples involved. Subsequently, more efficient shortcuts like sorting greatly increased the utility of mapping techniques. In sorting-based MDS, participants need not make all of the possible comparisons; rather they simply group the stimuli into as many or as few groups as they need to organize the stimuli according to their own criteria. This also allows perceptual mapping to be used with highly fatiguing stimuli like odors or cheeses (Lawless and Glatter, 1990; Lawless *et al.*, 1995). The interpretability of perceptual maps can be further increased by adding a second step in the data collection process. Once participants have formed their groups, they can be asked to provide attributes (descriptors) for their groups. Mean data from frequency counts or attribute ratings for the most common descriptors can then be regressed into the perceptual maps. The resultant map thus contains both points for the individual stimuli as well as vectors for the relevant descriptors (**Figure 5**).

As an alternative to sorting-based MDS, a technique known as projective mapping or napping has been developed (Pagès, 2005). Although the participant task and the multivariate analysis are slightly different to sorting, the general goal is the same. The participant is provided a large two-dimensional (2-D) space (a *nappe*, French for tablecloth), and using their own criteria they are instructed to put similar items close together, with less similar items placed farther away. The x–y coordinates of the individual stimuli in this space are then reduced to a consensus perceptual map using multifactor analysis (MFA). Characteristics of the groups as generated by participants can be included as attributes and counts of descriptors can act as data that can be regressed into the space. This technique has been used with a variety of products, including apples, cheeses, citric juices, chocolates, and wine (Bershaw and Heymann, 2010; Kennedy and Heymann, 2009; Nestrud and Lawless, 2008, 2010). Notably, use of a 2-D space to collect data from participants does not restrict the solution

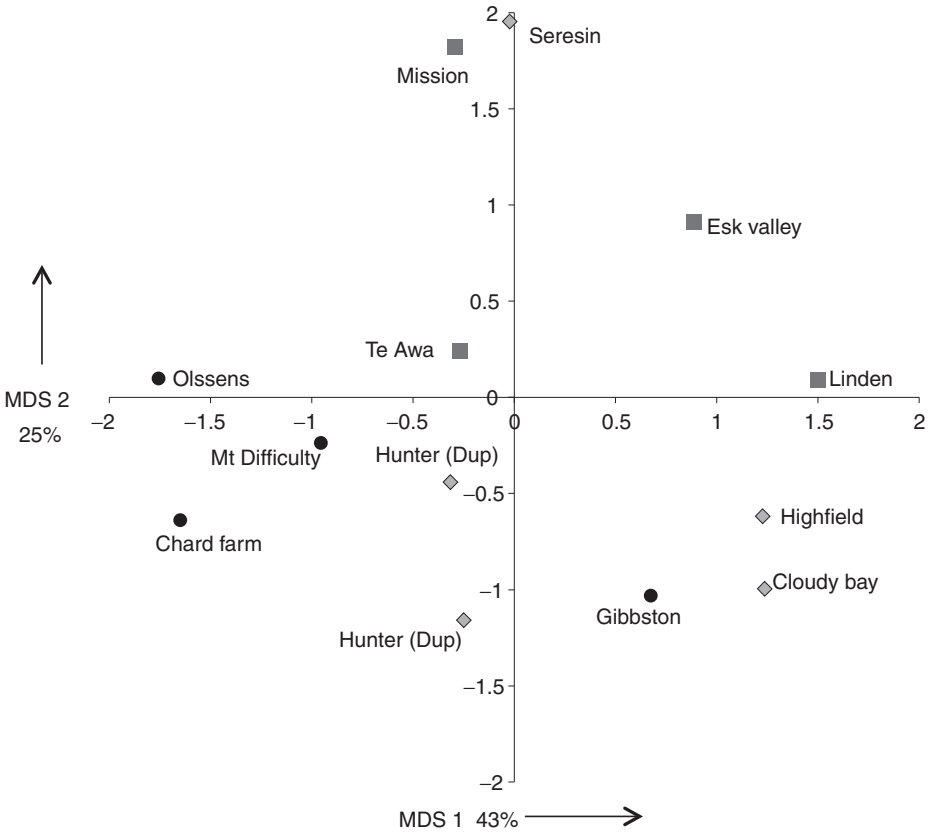

Figure 5 An example of a two-dimensional map based on sorting of 13 New Zealand Chardonnay wines based on similarity of flavor by a group of 27 wine experts/semiexperts, who also provided descriptors for the most prominent sensory characteristics. Physicochemical data for these wines were also provided by the winemakers. MDS 1, accounting for the largest share of variance, was found to be positively associated (right-hand side) with woody and caramel notes, volatile acidity, and negatively associated with pH. MDS 2 was positively associated with alcohol content and Brix (sugar content), whereas negatively associated with citrus notes. The different symbols represent different wine regions and the spread for each symbol suggests that region was not a significant determinant of how the wines were perceived by the panel (Springhall, 2002).

to two dimensions, as the analysis can successfully extract higher dimensionality from the data (Nestrud and Lawless, 2011). Open source tools to perform these analyses are available (Le and Husson, 2008).

Napping is considered a user-friendly procedure because little or no training is required. Moreover, relatively high numbers of samples (10–12) can be evaluated in each session. Although napping has the potential to uncover criteria that might be more relevant to consumers than those provided on an attribute list, there is a bias toward using hedonics as a major criterion. Hence, liked samples are typically positioned close to each other. In contrast, trained subjects tend to use nonhedonic criteria, which leads to better discrimination between samples.

Another recent approach to eliciting details of product attributes that are directly relevant to consumers is the check all that apply (CATA) method (Adams *et al.*, 2007). CATA allows consumers to decide which attributes from a list apply to the sample being assessed. The list itself can be generated by other consumers or a trained panel, but the selection process avoids any bias that might be inherent in having to respond to all attributes. As an example, a recent study used consumers to assess a series of milk desserts (Ares *et al.*, 2010). For each sample, consumers rated overall liking and selected from 17 hedonic and sensory attributes provided by a previous study in which consumers described vanilla milk desserts. The data consist of frequencies of the use of particular terms from the list: in this case, the most common terms were 'sweet,' 'soft,' 'yummy,' 'intense chocolate flavor,' and 'thick.' These counts were then submitted to factor analysis in order to determine which terms best discriminated between the different products.

A potential limitation of this approach is that the data appear to show only that any particular attribute is relevant to greater or lesser degrees. To what extent is this able to discriminate between products? A recent study compared CATA alone, CATA plus intensity ratings of the attributes, and Napping (Reinbach *et al.*, 2014). In fact, all methods produced a similar outcome and it was demonstrated that frequency of selecting a particular attribute provided a good estimate of its rated intensity, rendering the rating process unnecessary. Napping did produce a more varied and larger set of attributes because the consumers were not limited to a limited list of terms. The authors recommended that Napping was better suited to cases where unique, intuitive, or creative descriptors were needed (e.g., explorative studies) and that CATA was better able to increase awareness of certain attributes, in turn, aiding the consumer in performing the descriptive profile. Moreover, CATA is apparently more rapid to perform and hence better suited to studies with large numbers of consumers.

Combining Consumer and Descriptive Data

The outputs from descriptive analyses are often statistically combined and mapped together with consumer data as a means of providing explanations of consumer preferences in terms of sensory attributes. The so-called preference maps provide a relatively straightforward means of linking variation in attributes with variation in measures of acceptability (Greenhoff and Macfie, 1994; McEwan, 1996).

The maps can be constructed from sensory (or instrumental or product formulation) data onto which the consumer preference data are plotted, referred to as an external preference map. Internal preference maps, by contrast, map first the underlying dimensions of the preference data. The consumer data can be hedonic ratings or other types of data, for example, CATA counts. The rationale behind preference mapping is that if consumers like products to different degrees, then they must base this on different intensities of sensory attributes in the products, even if they are unable to describe these attributes. Thus, if one knows how products vary from the external data, they can infer the reasons for liking differences. Once the map is constructed by the external data, acceptance data for each individual are regressed against the product coordinates obtained from these data. The relationships between sensory attributes (and products) can be linear or quadratic, in the latter case reflecting an optimal sensory/ingredient level. An external map can be created by mapping all the relevant sensory or other attributes of the products (e.g., Daillant-Spinnler *et al.*, 1996; Prescott *et al.*, 2001). However, preference data can also be mapped onto the underlying dimensions of the sensory data derived using a technique such as PCA (see Section Descriptive Profiling/Analysis) (Menichelli *et al.*, 2012).

Mapping individual consumer data onto a space created by sensory data will facilitate the discovery of any consumer subgroup or cluster that perhaps views the products in different ways (e.g., Geel *et al.*, 2005). An average preference vector – essentially a direction of increasing preference – can also be derived from the individual ratings. Relating this vector to the product and their sensory attributes potentially allows an easy visualization of unoccupied 'spaces' on the map close to the point of maximum preference that could represent opportunities in terms of new products or improvements for existing products.

Individual Differences

As noted in Section Affective Consumer Methods, consumer responses are characterized by their high variability as well as their changeability from one test session to another. To some extent, this reflects the fact that consumers' decisions are complex, with preferences changing according to circumstances. Just as importantly, however, consumers themselves vary from one another in myriad ways. Certainly, consumer testing frequently stratifies participants according to sex, age, city/urban, and product usage, as these factors are recognizable sources of variation. In addition, however, there are potentially very many other variables that will have an impact on consumer preferences.

Just as some individuals are 'color blind,' it has been known for almost a century that some individuals may be 'taste blind' or 'smell blind' to specific compounds. This means that the same stimulus may differ in its fundamental perception across two individuals due to biological differences. Over the past 20 years, new research in taste biology and molecular genetics has provided new insight into the understanding of individual differences in chemosensation. These differences are not merely of academic interest, as emerging data indicate that they may be sufficient to influence food choice and dietary habits, at least in some contexts.

Recent research has identified, for example, consistent subgroups within populations that vary in terms of bitterness

sensitivity (Dinehart *et al.*, 2006) and liking of sweetness (Mennella *et al.*, 2011), both of which have been shown to relate to food preferences. A substantial minority of women in the USA are thought to be restrained eaters, that is, cognitive factors cause a disconnect between what they like and what they allow themselves to eat. Hence, understanding both food preferences and food choices is complex and nuanced. For example, variation in the bitter taste receptor TAS2R38 has been shown to predict differential intake of alcohol and vegetables (e.g., Duffy *et al.*, 2010; Hayes *et al.*, 2011a,b). Nor are these differences restricted to a single genetic variant in a single gene.

Other recent reports indicate the bitterness of the non-nutritive sweetener Acesulfame-K (Allen *et al.*, 2013), the grassy odor of cis-3-hexenal (Jaeger *et al.*, 2012), the meat defect boar taint (Keller *et al.*, 2007), and the creaminess of starch (Mandel *et al.*, 2010), which all differ across individuals as a function of genetic variation. So too does the intensity of food pungency and taste and one's ability to detect variations in tastes within products (Lee *et al.*, 2008; Prescott *et al.*, 2004a, b). This remains an active area of research and interested readers should see recent reviews (Hayes *et al.*, 2013; Prescott, 2006).

Other individual difference factors whose etiology is unknown have also come to light. The extent to which an individual responds to temperature changes on the tongue by perceiving tastes appears to predict not only responses to tastes themselves (Green and George, 2004) but also some food preferences (Bajec and Pickering, 2010). Patterns of hedonic responses over varying sweetener concentrations (Pangborn, 1970) may also be a good predictor of sweetness preferences within foods (Mennella *et al.*, 2011).This same factor, together with global bitterness sensitivity, has also been shown to influence the extent to one forms likes/dislikes for flavors when these are paired with sweet or bitter tastes, respectively (Yeomans *et al.*, 2009).

These academic studies have important implications for the practice of sensory science. They suggest that individual differences in consumer responses are not simply noise, but rather that one may be able to pin down the origins of a proportion of the variability in one's measures. Because many of the recent findings appear to be directly related to one's experience of foods, they may be better predictors of preferences than factors such as sex or age. In other words, should one be stratifying their consumer samples based on perceptual/preference segments? The food industry manufactures different product types for young and adult consumers. Do these recent findings from sensory science suggest that it would be appropriate to provide different sensory formulations based on different responses to sensory properties? Certainly, this may be happening already with some products. The fact that instant coffees come in different blends that vary in bitterness and flavor strength suggests an industry response to consumers who wish to self-select on the basis of their responses to these sensory qualities (Geel *et al.*, 2005).

Issues of Good Sensory Practice

Sensory science applications are first and foremost problem-solving exercises that require careful definition of the problem: What is the evaluation meant to achieve? To what use will the results be put? Once these questions are answered, the sensory specialist is able to define the method and then analyze and interpret results consistent with objectives and methods.

Lawless (e.g., Lawless and Heymann, 2010) has proposed a 'Central Dogma' that should guide sensory evaluation. The key aspects of this are that:

1. Test methods should match objectives. Analytical methods are for determining, describing, and measuring differences; hedonic measures are used to measure acceptability/liking.
2. Different people are used for different objectives. Trained/experienced panels are asked to ignore their 'gut response.' It is unimportant whether or not they like a product. Consumers are very poor at analyzing or describing. Therefore, do not mix analytical and hedonic measures with the same group.
3. As an extension of this last point, claims about acceptability ('the best product') should not be made if consumers have not been used.

Sensory Evaluation Facilities

Details of design specifications and ideal environmental conditions for panel training facilities, testing booths, and sample preparation areas can be found in the relevant standards (ISO8589, 2007) as well as in sensory evaluation texts (Lawless and Heymann, 2010). In general, however, the design and development of a sensory testing facility first requires consideration of its location within the larger building or complex in that it needs to be readily accessible to participants. If participants are not employees who are already on site, locating near an entrance adjacent to sufficient visitor parking is ideal. Test spaces should minimize distractions, such as noise and background odors; this means care should be given to isolate the testing facility away from smokehouses, bottling lines, cafeteria kitchens, machine shops, loading docks, etc. It is also important to consider the facility's location relative to mechanical systems such as air handlers, processing equipment, and cold storage units. Depending on the nature of materials being tested, it may be important to include oversized air handling to insure sufficient changeover in room air in order to eliminate background odors.

At its simplest, the evaluation area of a sensory testing facility can be a large multifunctional space. Many sensory tests place a strong emphasis on independent evaluations by the participant. However, there are other times when the participant needs to interact with the sensory professional and/or other participants (e.g., trained panels described in Section Descriptive Profiling/Analysis). Accordingly, most custom-built sensory facilities have two basic areas: individual booths and a group discussion room. Although permanent booths are preferable, effective participant isolation may be achieved in a multipurpose space with simple table-top dividers that collapse when they are not needed. Individual booths, whether temporary or permanent, are used when it is advantageous to keep panelists from interacting, as this could potentially introduce noise or bias. A discussion room is used most often for training panelists and other tasks where the interaction between the sensory professional and participants or between participants is encouraged. Critically, the evaluation area,

whether a booth or a large room, should be clean and uncluttered and should have easy access to the sample preparation area.

Ethical Issues

The vast majority of sensory tests do not represent risks beyond 'the ordinary risks of daily life' and may, therefore, be exempt from additional regulatory oversight. However, legal exemptions do not remove ethical responsibility from the sensory specialist. Specifically, participants need to be volunteers who are fully informed of the potential risks of participation, in accordance with the Declaration of Helsinki. In industrial settings, the potential for coercion is especially high when employees are used as participants. They may feel that they are expected to participate in tests and will be marginalized within the organization if they do not 'volunteer.' In academic settings, depending on the institutional review board, the sensory specialist may also need to get a signed copy of an informed consent form before participation. In some settings, implied consent, where participants read the consent form and then agree to move forward with the test, is acceptable.

The sensory specialist should not be complacent that they are 'just testing foods,' as improperly stored or prepared foods may present real risks to health to participants and potential financial losses to the company if injured parties take legal action. New products may also include novel or experimental ingredients that are not yet classified as generally recognized as safe – this needs to be disclosed to potential participants in order to allow them to make an informed decision about whether to participate. Also, the concept of risks does not include just physical harm – as sensory science continues to borrow and adapt tools from psychology to study emotion and personality, it is important to remember that harm may include potential emotional/psychological distress that may result from a focus on personal emotional responses or personality characteristics. Accordingly, a basic risk assessment is merited for all sensory tests. For additional guidance on these issues, see Kemp *et al.* (2009) or recent policy statements by the UK Institute of Food Science and Technology.

Participant Selection

The nature of the participant depends on the goal of the test. Different selection criteria can thus be applied to obtain appropriate participants for a given test. When individuals fail to meet screening criteria, tact is required to avoid offending the individual, as they may be appropriate for a future test. For hedonic tests, it is reasonable and common to select frequent users of the product, regardless of taste acuity. Consumer tests may also select on demographic criteria like age, sex, or income. For discrimination tests, one may screen participants to insure that they are not anosmic or ageusic for the compound of interest or for overall ability to discriminate between samples. Finally, there may be ethical considerations to consider. Regardless of self-reported use, testing certain products in those whose diets are restricted due to illness may not be advisable. Religious objections to some foods should also be considered.

How Many Participants?

The issue of typical numbers of panelists was raised in Sections Descriptive Profiling/Analysis and Affective Consumer Methods. In fact, in any sensory test, the number depends on a range of factors, specifically the actual degree of difference between samples as well as their degree of stability (batch-to-batch variation), the sensitivity of the participants, and the extent to which external factors that contribute to 'noise' (statistical error) can be controlled. Participant's sensitivity can be dramatically improved with training, which is why highly trained panels often contain only 10–12 individuals. Training, of course, produces panelists that are atypical of consumers. Although consumer tests are facilitated by insuring that participants are motivated and not subjected to fatiguing testing procedures, their inherent variability is dealt with by having much larger panel sizes. Having more panelists decreases the impact of factors that produce variability. In any sensory evaluation, 'noise' can be reduced via precise instructions and controlling any factor that might detract from the participant's focus on the samples being evaluated.

Each of these factors is an influence on the statistical power of the procedures (Cohen, 1988). A key concept underlying statistical power is that finding differences between treatments (in the case of sensory evaluation, products or samples) involves a trade-off between Type-I and -II errors. The former are produced when a statistical test tells one that a significant difference is present (at some probability level, usually 0.05) but that this is spurious – in fact, it was one of the 5 cases in 100 that shows up by chance. Type-II errors are the opposite: the test tells us that no differences have occurred when they may actually be evident if the test is done again, especially if either the statistical 'noise' is reduced or the number of participants is increased, or both. Increasing the alpha level above 0.05 would also reduce the Type-II error risk, but by convention this tends to be fixed.

Although increasing statistical power (and hence one's ability to detect differences) is very often desirable, it does raise other issues. In particular, it is important to know the pay off for detecting real differences versus detecting false differences. In other words, just how large a difference is needed to be shown? For instance, it might be shown with sufficient numbers a statistically significant difference between samples, even though, on average, they were rated only 3% of the scale length apart. Is such a significant result meaningful – will it reflect different patterns of food choice, for example?

Sample Preparation, Serving, and Tasting

Apparently mundane issues related to sample serving and presentation are critical for the execution of successful sensory tests. Seemingly trivial details, like the serving size or temperature, the order samples are presented, the timing of samples, or the protocol for rinsing between samples can have very large effects that swamp real differences across products.

Common pitfalls in sensory tests include variable serving sizes, serving temperature, and imprecise control over sample identity. Different sample sizes can influence not only the intensity of the sensation but also the rate at which samples cool or melt. This presumes that samples were presented at the same temperature initially, which may not be a valid assumption if the sensory specialist is not careful. Samples served at different temperatures may not only differ in aroma release or flavor intensity but also in appearance. So, although panelists are often tested blind to the brand of products, there are often sensory cues other than those being tested that distinguish samples. Commonly, samples are presented under red light to mask variations in appearance when this is irrelevant to the purpose of the test.

Instructions given to participants need to be pretested to remove ambiguity. Swallowing a sample produces different outcomes from expectorating the sample in many cases. But even when all panelists follow an instruction to swallow, care needs to be taken to insure that the sample amount remains the same. For example, Prinz and De Wijk (2007) instructed participants to take a single sip of vanilla custard via a large bore straw, and the mean volume ingested varied from 0.4 to 35 ml of sample. As might be expected, they also found sip size was significantly associated with differences in attribute ratings, and more importantly, the effect of sip size differed across attributes.

The number of samples to be served per testing session is a matter of judgment by the sensory specialist. This will depend on not only the flavor strength of the sample but also their pleasantness and the extent to which the sample qualities persist between samples. A key issue with the testing of samples with significant spiciness, for example, has been the fact that the heat of oral irritants such as chili may persist for 10 min or more once the sample has been swallowed or expectorated (Allison *et al.*, 1999). The length of time between samples can also influence ratings (e.g., Guinard *et al.*, 1986). Careful thought also needs to be given to the rinse agent and rinsing protocol between samples (Lee and Vickers, 2010).

Finally, the presentation order of samples is crucial, given the occurrence of contrast and context effects. Care should be taken, therefore, to insure that panelists receive samples according to appropriate randomization or counterbalancing protocols (Macfie *et al.*, 1989). Additional information on the issues presented in this section is provided in relevant sensory texts (Kemp *et al.*, 2009; Lawless and Heymann, 2010; Meilgaard *et al.*, 1987) and ASTM/ISO standards for sensory testing.

Conclusion

This article on sensory science covers only some of its basic issues and practices. The sophisticated analysis of sensory data from trained panels and consumers represents a large and growing part of the armory of sensory specialist, so much so that a new field – Sensometrics – has developed to meet the demand. The so-called objective measures of sensory perceptions and preferences, including brain scanning with functional magnetic resonance imaging techniques, are being explored academically and commercially, although there is nothing to suggest yet that these approaches will be better predicts of what consumers will choose to eat. Importantly, although neuroscience has begun in recent years to increasingly focus on human emotional states, it may bear fruit in time in terms of better understanding of what is measured. For those interested in understanding sensory science in greater depth, the following journals are the best reflection of current and future trends: *Food Quality and Preference*, *Journal of Sensory Studies*, *Appetite*, *Physiology and Behavior*, *Chemosensory Perception*, and *Chemical Senses*.

Glossary

Climate change impact assessment Climate change impact assessments are using crop models to study the impact of projected climate change scenarios on agricultural production systems.

Crop models Crop models are a formal way to present mathematical algorithms that represent quantitative knowledge of crop growth in interaction with the environment.

Cropping systems analysis Cropping systems analysis combines crop modeling of atmosphere–crop–soil systems with field experimentation to increase the understanding of agricultural systems.

Dynamic simulation modeling Dynamic simulation modeling is the computer-assisted calculation of crop development and growth processes over time.

Phenotype simulations Phenotype simulations investigate crop trait impacts and are used to optimize crop characteristics for specific growing environments for agronomic and breeding support.

Simulated water-limited yield potential Simulated water-limited yield potential is a crop yield under rain-fed (water-limited) conditions in absence of pest, diseases, and weeds.

Simulated yield potential Simulated yield potential is a crop yield without water or nutrient limitations in absence of pest, diseases, and weeds.

Yield forecasting Yield forecasting combines dynamic simulation modeling with seasonal rainfall and temperature forecast to predict yield over a 39 month time frame.

Introduction

Crop modeling is a formal way to present mathematical algorithms that represent quantitative knowledge about how a crop grows in interaction with its environment. Crop models often simulate different aspects of a crop using daily weather information such as solar radiation, maximum and minimum temperatures, and rainfall. Other information needed for a crop simulation includes soil characteristics, initial soil conditions, cultivar characteristics, and crop management. Using these different data, the models can simulate the dynamics of crop development (or phenology), biomass accumulation, yield, water, and nutrient uptake (Table 1). Crop simulation models are a powerful means to capture the quantitative information of agronomy and physiology experiments in a way that can help explain and predict crop growth and development. These models have made a substantial contribution to agriculture. Crop models help explore dynamics between the atmosphere, crops, and the soil, and can be used to test quantitative hypotheses against reality. Also, they are valuable because researchers can use them to extrapolate data beyond field experimentations, assess the impacts of climate change, and test adaptation to climate change (Figure 1). Crop models are also a central part of decision support systems (DSS) for agriculture, which are computer models designed to assist farmers in making decisions for the season. Also, crop models are part of larger dynamic agricultural model systems that include economics and human behavior.

History of Crop Models

Crop simulation modeling started in the 1960s when scientists developed the first mathematical relationships between biomass growth and solar radiation (De Wit, 1965; Duncan *et al.*, 1967; Monteith, 1965). The first crop models were published

Table 1 List of processes commonly simulated in crop models. Models often incorporate these processes and their mathematical descriptions in various ways

Common processes in crop models	*External factors*
Phenological stages (anthesis, maturity, pod set, seed set, tuber initiation)	Temperature, day length
Crop growth (aboveground biomass, leaves, stems, pods, seeds or grain yield, tubers, roots, Harvest Index)	Solar radiation, temperature
Potential and actual evapotranspiration, crop transpiration or water uptake, soil evaporation	Solar radiation, temperature, rainfall, irrigation
Nutrient uptake (mostly nitrogen)	Nutrient supply
Stresses (water deficit, nitrogen deficit, low or high temperature stress)	Rainfall, temperature, nutrient supply

 doi:10.1016/B978-0-444-52512-3.00233-3

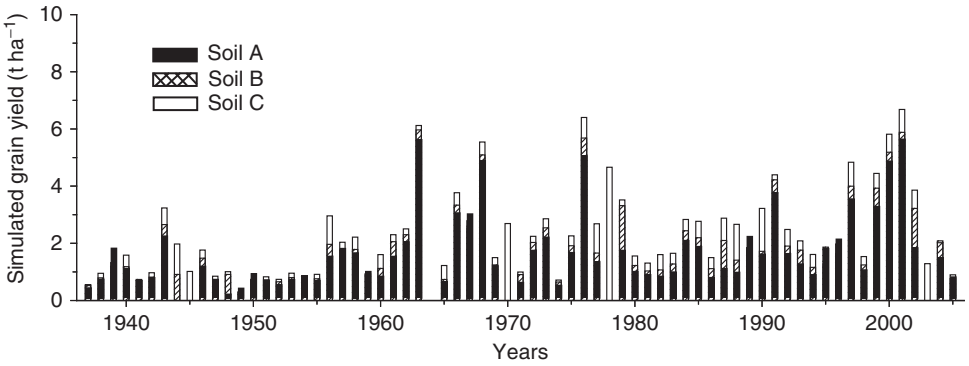

Figure 1 Simulated wheat grain yields to explore the wheat production potential of a current nonagricultural region. Simulations are from 1937 to 2005 for a location west of the current wheat-growing region of Argentina, which received increasing rainfall over the past 70 years, for three soils using a current modern cultivar and a summer fallow. The crops were sown every year on June 5, with a 100 kg N ha^{-a} fertilizer application. Simulations were reset each year; simulated yield variation and trend are because of rainfall variability and trend. Reproduced from Asseng, S., Travasso, M.I., Ludwig, F., Magrin, G.O., 2013. Has climate change opened new opportunities for wheat cropping in Argentina? Climate Change 117(1/2), 181–196, with permission from Springer.

in the 1970s (Loomis *et al.*, 1979). Monteith (1977) described a simple linear correlation of biomass and intercepted light, which led to further crop modeling in the 1980s and 1990s, and included the development of the crop models ARC-WHEAT1 (Porter, 1984), CERES-Wheat (Ritchie *et al.*, 1985), and the Dutch model Simple and Universal Crop Growth Simulator (van Laar *et al.*, 1992). Initial applications of crop models in agricultural research started in the early 1970s (Hesketh *et al.*, 1971). In the early 1980s, Farquhar *et al.* (1980) published a more detailed leaf photosynthesis model, which is still used in some crop models. Most crop models at that time concentrated on comparing models with experimental data to further improve the simulation of cropping systems. Crop models began to assess the impacts of climate change when researchers included data on the effects of atmospheric CO_2 in the models (Rosenzweig and Parry, 1994).

In the 1990s, crop models for various crops were merged into crop modeling platforms, including Decision Support System for Agrotechnology Transfer (DSSAT) (Jones *et al.*, 2003) (http://dssat.net/), Agricultural Production Systems Simulator (APSIM) (Keating *et al.*, 2003) (http://www.apsim.info/Wiki/), CropSyst (Stöckle *et al.*, 2003) (http://www.bsyse.wsu.edu/CS_Suite/CropSyst/), Wageningen crop models (van Ittersum *et al.*, 2003), Simulateur multidisciplinaire pour les Cultures Standard (STICS) (Brisson *et al.*, 2003) (http://www7.avignon.inra.fr/agroclim_stics_eng/), and Environmental Policy Integrated Climate model (EPIC) (Kiniry *et al.*, 1995). In the 2000s, researchers also further advanced single-crop models. For example, the SIRIUS model (Martre *et al.*, 2006) and WheatGrow model (Pan *et al.*, 2006) included grain quality simulations, and the RiceGrow model considered plant architecture (Zhu *et al.*, 2009). Over the past 10 years, researchers developed more crop models that vary in their approach and complexity, including System Approach to Land Use Sustainability (SALUS) (Basso *et al.*, 2001), AquaCrop (Steduto *et al.*, 2009) (http://www.fao.org/nr/water/aquacrop.html), HERMES (Kersebaum, 2007), Model of Nitrogen and Carbon Dynamics in Agro-ecosystems (Nendel *et al.*, 2011), and Lund-Potsdam-Jena Managed Land Dynamic Global Vegetation and Water Balance Model (Bondeau *et al.*, 2007) (http://www.pik-potsdam.de/research/projects/lpjweb). Today, at least 30 models exist for wheat, 19 for maize, and 13 for rice (www.agmip.org). Although crop model testing with field experimental data is still an important part of crop modeling to further improve the models (Asseng *et al.*, 2004), crop models are increasingly applied in simulation experiments.

Key Processes in Crop Models

Key processes simulated with crop models include crop development (phenology), biomass accumulation, yield, water, and nutrient uptake (**Table 1**).

Main Crop Model Systems

Based on the web of knowledge, the most cited crop models include DSSAT (Jones *et al.*, 2003), APSIM (Keating *et al.*, 2003), CropSyst (Stöckle *et al.*, 2003), models from Wageningen (van Ittersum *et al.*, 2003), and EPIC (Kiniry *et al.*, 1995). Most crop models have a modular structure, with crop modules for many different crops linked to soil water, soil nitrogen, and carbon modules. These crop models (a crop module linked with soil modules) have been extensively tested across field experiments and used in many applications.

Crop Model Links to Other Systems

Crop models are often integrated into other model systems, such as DSS (Hearn *et al.*, 1981), farm economic models (Stoorvogel *et al.*, 2004) and human-landscape interactive models (Matthews, 2006).

3-D Crop Models

In the 1980s, Prusinkiewicz and Hanan (1989) used theories ('rewriting rules') by Lindenmayer (1968) to start developing model simulations of dynamic plant architecture. Initially, these models described the 3-D architecture of plants without considering the plant physiological processes and interactions with

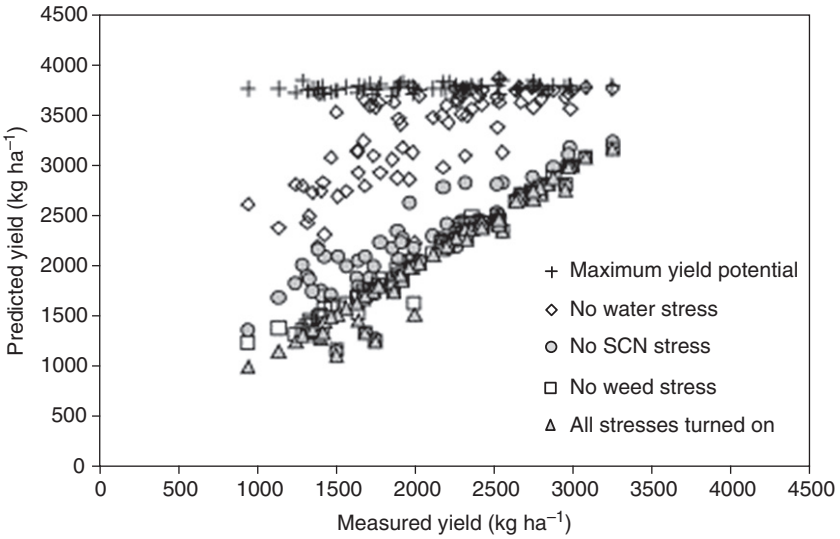

Figure 2 Maximum potential soybean yield, along with variations in predicted soybean yield as affected by soybean cyst nematode (SCN), weeds, and water stress. Reproduced from Batchelor, W.D., Basso, B., Paz, J.O., 2002. Examples of strategies to analyze spatial and temporal yield variability using crop models. European Journal of Agronomy 18(1–2), 141–158.

the environments. Recently, these 3-D architectural models are becoming connected with physiological algorithms from crop models to create functional-structural models (Vos *et al.*, 2007).

Crop Agronomy

Through the decades, agronomy has evolved from field management to an integrated discipline that includes genetics, plant physiology, agricultural meteorology, climatology, soil science, remote sensing, and computer science. As a consequence, scientists are increasingly applying mathematical, biological, chemical, and ecological principles in agronomy. Simulation models have become a tool that integrates different areas of agricultural research. In turn, the models help further research and provide information to assist farmers produce more food on less land and reduce the environmental impacts of agricultural practices.

Yield Gap

Crop yield potential is defined as the crop yield obtained when a crop is grown without limits on water or nutrients and in the absence of any pests, diseases, and weeds. Therefore, a crop's yield potential is a function of solar radiation, air temperature, and crop genetics at a specific location (van Ittersum *et al.*, 2003). In rain-fed environments (agricultural environments that must rely on rainfall for water), the potential yield concept is adjusted to a water-limited yield potential because crop growth and other factors affecting yield potential are defined by the water supply and soil characteristics (Lobell *et al.*, 2009). A crop's yield potential can be experimentally determined in a field or obtained from well-managed farmer fields. However, this is usually costly or hard to achieve (Lobell *et al.*, 2005). Crop models have been used to estimate yield potential and water-limited yield potential for specific fields, farms, and regions (Lobell *et al.*, 2009). In addition to quantifying a potential yield, crop models have been used to understand the reasons for a yield gap, or the difference between actual and potential yield. For example, Batchelor *et al.* (2002) used a crop model to attribute portions of a yield gap to disease, weeds, and water stress effects (**Figure 2**).

Nitrogen Management

Adequate nitrogen (N) management is an important challenge faced by researchers in agronomy. There is a need to produce more food with fewer inputs and minimal environmental impact. The nutrient needs of farmers' fields vary over time, and different areas of the field may need different levels of nutrients. Because of this temporal and spatial variability, studies must include information on multiple locations over a long time period. Using this information, researchers can develop nitrogen fertilization strategies specific to crops and the environment where they are grown.

Crop models can simulate the long-term effects of N on crop growth and yield and the interactions over time on daily crop growth and development (Batchelor *et al.*, 2002). Asseng *et al.* (2001a) used a crop simulation model to estimate the potential wheat crop response to N management over many locations using 80 years of historical weather data. The study showed that N use efficiency of a crop varies with rainfall zone, rainfall season, soil type, and initial soil water conditions. These results would have been difficult to estimate from field experiments alone. Although crop growth is affected by N fertilizer, grain quality also often depends on N supply. Several simulation studies have used crop models to understand the effects of N management practices on both crop growth and grain protein accumulation as a grain quality measure (Martre *et al.*, 2003).

Irrigation

Water is a main factor that limits crop growth and yield in many parts of the world. In these places, rain is insufficient to

meet crop demand. To help these areas, scientists need a better understanding of the crop water balance and crops' yield response to water (Steduto *et al.*, 2009). The crop water balance is complex and contains several processes, such as rainfall, irrigation, rainfall interception by crops, surface drainage and runoff, soil evaporation, transpiration, and root water uptake (Tang *et al.*, 2009). Most crop models include these components of a water balance, which allows them to be applied to manage irrigation of crops (Singh *et al.*, 2008). For example, a crop model helped maximize yields for a wheat crop in northern Africa in an area that only had access to limited supplementary irrigation (Heng *et al.*, 2007).

Sowing

The choices made when sowing a crop are some of farmer's key management options. These choices include determining the cultivar, planting density, and time of sowing. The optimum sowing practice to maximize economic return is often difficult to quantify. Many factors interact during a crop season, and new cultivars are continuously being developed. Crop simulation models have been used to generate yield response functions that can help to evaluate how different sowing strategies affect the economic response of crop yield. For example, Paz *et al.* (2001) used a crop simulation model to identify the best soybean variety for a specific location. Batchelor *et al.* (2002) used a crop simulation model to estimate the best variety that will maximize a farmer's economic return. Asseng *et al.* (2008) used a crop model to identify optimal sowing dates and yield penalties from delayed sowing in a variable rainfall environment.

Seasonal Variability

Variability in the amount of rainfall in rain-fed agriculture is a major source of variability in grain yields. Forecasting the season type (e.g., wet or dry) can allow farmers to adjust crop management. In dry, low-yielding seasons, producers can save input costs, whereas in wet, high-yielding seasons they can increase inputs for a higher yield potential. Crop models can simulate many management practices using long-term historical weather records, allowing producers to optimize management strategies for season types based on the seasonal forecast. Hammer *et al.* (1996) combined a seasonal forecast with multifactorial long-term simulation experiments and showed that profits could increase up to 20% when adjusting crop management to Southern Oscillation Index (SOI) phases in the Queensland wheat-belt. Similarly, using El Niño Southern Oscillation (ENSO)-based forecasts for maize management in the southern US and Argentina could increase profits by US\$13–15 ha^{-1} (Jones *et al.*, 2000). Asseng *et al.* (2012) linked crop simulations with a coupled ocean-atmosphere Global Circulation Model (GCM) to manage rainfall season types in the southern part of the wheat-belt of western Australia, yielding an extra profit of AU\$50 ha^{-1} from improved crop management.

Spatial Variability

Spatial variations of weather, soil water, nutrient supply, and crop management impact farmers' yield and may cause agricultural externalities (e.g., environmental consequences from nitrate leaching into water systems). Region-specific nitrogen fertilizer strategies have been developed by combining crop models with spatial field information (Basso *et al.*, 2011). In one instance, a crop model linked with regional soil and weather variability was used to quantify the potential water access of cropping systems as the main source of salinity in areas without irrigation (Pracilio *et al.*, 2003). Using remote sensing data (remote sensing in agriculture is using aerial sensor technology to gain information about crops) allows researchers to learn more about the spatial variability in farmers' fields. For example, combining crop simulation at points in a field with remote sensing at a regional scale can extend the simulation of temporal variability to spatial variability across a field or region (Wang *et al.*, 2012). Two methods used to integrate crop models with remote sensing data include driving methods and assimilation (Moulin *et al.*, 1998). Driving methods are updating variables in a crop model using remote sensing observations, and assimilation is creating new parameters in a crop model using remote sensing observations. Both of these methods can help to improve crop management of spatial variability.

Rotation

Crop rotation is the agronomic practice of growing crops on the same paddock in sequence. It has several benefits for soil and crop systems. Beneficial effects include lower incidence of weeds, insects, and plant diseases, as well as improvements of soil physical, chemical, and biological properties. Improvements in the soil physical properties include better water holding capacity and aggregate stability, whereas the improvements in the biological properties include an increase inorganic matter, which replenishes soil nitrogen (N) and carbon. Crops grown in rotation reduce greenhouse gas emissions because of the lower amount of N fertilizer added. For example, if cereal crops follow a leguminous crop, the rotation can fix atmospheric N through rhizobacteria. The selection of crops used in rotations is often determined by the crop's commodity price. Farmers often return to continuous cropping systems despite the numerous advantages provided by rotating crops, especially if the specific crop prices are high. This decision has been an error over the long term. Crop yields have declined in continuous cropping systems, and there have been increases in input demands, leading to lower overall farm profitability.

Agronomists have studied yield responses to crop rotation and tradeoff analysis between yield and input demand in field experiments. Yield responses often vary across these field experiments. Crop rotations are affected by various factors such as soil type and fertilizer input in interaction with seasonal rainfall variability. This means a system approach using crop models can help to evaluate the carryover effect of carbon, nitrogen, and water in a rotation to optimize crop rotations for a specific environment. Several crop models can simulate the effect of crop rotations on yield and soil properties. The most common models used to simulate crop rotations are DSSAT, EPIC, APSIM, CropSyst, STICS, SALUS, and root zone water quality model (RZWQM). Each of these models can simulate

Table 2 Dominant insect and herbivores on upland cotton, *Gossypium hirsutum,* in the western US, the structures they feed on, and the type of injury[a]

Herbivore	*Fruiting structures*	*Leaves*	*Stems*	*Roots*	*Meristem tissue*	*Feeding injury and its impact on the host crop*	*Plant feedback to the herbivore*
Aphids and whiteflies		●				Sucking produces excreta that support sooty mold, which restricts light and photosynthetic activity	Phloem 'N' content impacts aphid and whitefly fecundity and dispersal
Armyworms	•	●	●	●	●	Chewing reduces vascular transport and reduced photosynthesis when feeding on leaves	Plant vigor and/or available leaf area impacts feeding, which impacts aphid growth rate
Boll weevil	●					Chewing supports secondary fungal pathogens, which in bolls damages developing lint; fruit abscission prolongs vegetative development	Fruit availability in different age classes impacts what the larvae consume. 'N' in consumed fruiting structures impacts diapause
Fleahopper spp.	●				•	Sucking causes fruiting structure abscission	
Bollworm and budworm	●	•			•	Chewing; fruit abscission prolongs vegetative development	Fruit availability in different age classes impacts what the larvae consume. 'N' in consumed fruiting structures impacts diapause
Lygus spp.	●				•	Sucking can cause fruiting structure abscission and meristem death; fruit abscission prolongs vegetative development	
Pink bollworm	●					Chewing can cause fruiting structure abscission	Fruiting structure age impacts larval growth rates
Spider mite spp.		•				Sucking and phytotoxicity to surrounding cells	Leaf 'N' content impacts dispersal rates and fecundity
Thrips	•	•				Surface rasping can cause cell death and decreased cell expansion	

[a]The larger black circles represent organs pest species predominantly feed on, whereas the smaller black circles represent organs pest species less frequently feed on.

crop rotations, soil, water and nutrient dynamics, and management strategies over multiple years. The benefits of rotations have been simulated and tested for a corn-soybean rotation in comparison with continuous corn in the US using the RZWQM reproducing the higher corn yield under corn-soybean rotation than under continuous corn (Ma *et al.*, 2007).

Linkages with Pest and Diseases

Most crops are exposed to injury from a range of crop herbivores (e.g., insects, mites, plant pathogens, and nematodes). Capturing the dynamics of biomass accumulation, phenological development, and yield requires that crop models present how the crop is impacted by the physical environment and management inputs, as well as how it is impacted by dominant herbivores. Crop models need to have a structure that links each pest species to the plant organs that are directly impacted. The linkage (also referred to as 'coupling points') must allow the host crop to respond to the herbivore, as well as impact the development, fecundity (potential reproductive capacity), survivorship, and, in some cases, immigration/emigration of the pest species.

Interactions between pests and crops are quite varied as Table 2 illustrates for cotton, *Gossypium hirsutum.* In Table 2, the circle size represents the degree to which several insect and mite species feed on the plant organs. The two-way interaction between the crop and each of its dominant insect herbivores illustrates the dynamic nature of crop and pest interactions (Table 2).

The physical environment and the biological nature of the crop-pest interaction determine the manner in which a pest and its host crop are linked. Because interactions between pests and crops are complex, including these relationships in crop models requires many different physical factors of the crop and pest species. These physical factors include hourly canopy and soil temperature (pest species in general), the canopy vapor pressure/relative humidity gradients (surface inhabiting plant pathogens), photo flux density within the crop canopy and at the soil surface (weedy species), and water and nutrient availability within the soil (soil-dwelling insects, root-inhabiting nematodes, soil-borne plant pathogens).

Mapping these interactions in crop models also requires crop-based variables for each pest species. This data includes the density, mass, and nutrient content of each age class of each organ type (roots, stems, leaves, fruit) that serves as food for the pest. Other pest variables needed that are specific to the host plants include the type, density, age class, and mass of organs injured by each pest species, and the survivorship probabilities for injured organs. These variables allow feedback from the pest species to the host crop. For example, feeding by a leaf-chewing insect reduces the leaf area, which impacts light distribution throughout the canopy, photosynthesis by uninjured leaf tissue, and availability of metabolites for expansion of uninjured and injured leaves, and other crop structures. Each age class and type of leaf-feeding pest typically consume a predictable amount of mass. This

translates to the amount of leaf mass consumed changing dynamically with pest density and age class distribution, and the stage of crop growth during which the herbivore occurs.

A number of cropping systems have modeled the links between crop and pest species, including leaf spot on wheat and soybeans (Boote *et al.*, 1983), bollworm/budworm and spider mites on cotton (Ives *et al.*, 1984, Wilson *et al.*, 1991) rust and early leaf spot on peanuts (Savary *et al.*, 1990), and blast and water weevil on rice (Wu and Wilson, 1997).

Intercropping

Intercropping is defined as the agronomic practice of growing two or more crops on the same field at the same time. Crops selected for intercropping normally have different abilities to use the resources available for growth, which leads to yield advantages and increased stability compared to a single crop in a low input system. The use of high-yielding cultivars, increased mechanization, and increased fertilizer and pesticide use eliminated intercropping from most farming systems, with the exception of some regions in Africa and Asia (maize and cowpeas) or crops intercropped with agroforestry systems. The principles of crop models are also applied in intercropping models to show how different species combine and compete for light, water, and nutrients (Corre-Hellou *et al.*, 2009).

Kropff and van Laar (1993) described the ecophysiological model INTERCOM, which was one of the first models developed for competition between species. The model was mainly designed to evaluate the impact of weed infestation on crops. The model consists of a set of individual growth models (one for each competing species) that calculate the rates of growth and development for species based on environmental conditions. Under favorable conditions, light is the main factor determining the growth rate of the crop and its associated intercrop (i.e., weeds). The model calculated daily soil water balance accounting for plant-available water. If plant-available water dropped below a critical level, transpiration and growth rates of each species were reduced. Another example of an intercropping model is APSIM, which allows competition for resources (e.g., solar radiation, water, nitrogen) between two crops grown on the same field at the same time. Biological modules in APSIM compete on the daily time step through a set of allocation rules for resources. Adiku *et al.* (1998) used the APSIM model to compare a maize and cowpea intercropping system with these crops grown in monoculture for two savanna zones in Ghana. That study showed that for a sustainable production, intercropping maize and cowpea together with a modest fertilizer application was generally the better cropping system.

Natural Resources Management

When applied to agriculture, natural resources management (NRM) refers to the sustainable use of soil, rainfall, irrigation, and nutrients. Traditional crop management is aimed at increasing agricultural productivity alone. In the NMR framework, crop management to increase productivity is continued, but practices are adopted to maintain the long-term sustainability and integrity of agriculture systems. NRM has become increasingly important in the last decades as a result of soil degradation. Crop models can help farmers develop strategies to increase crop productivity without negatively impacting the basis of production and externalities. For example, a crop model has been used to identify optimal N fertilizer application rates for different management zones in a farmer's field (Basso *et al.*, 2011). The management zones were identified from long-term yield maps, remote sensing, and soil chemical and physical properties, which were then used as parameters for the crop model. The crop model simulated the cropping system for a range of N fertilizer applications. This helped to identify zone-specific N management strategies that result in the best yield with the least N leaching across the field (Basso *et al.*, 2011).

Soil Constraints

Although soil water and nitrogen effects on crop growth are included in most crop models, a number of other soil constraints are less commonly included (Probert and Keating, 2000). These include erosion, salinization, acidification, compaction, and water-logging, which are less understood. A range of erosion models have been developed that vary in complexity. Most of the erosion models are applied to environmental engineering, and a few have been included in crop models. For example, the EPIC model (Izaurralde *et al.*, 2006) and the APSIM model (Keating *et al.*, 2003) include routines that consider the impact of erosion on crop productivity. Some crop models consider the effects of soil compaction through a soil hospitality factor. For example, Wong and Asseng (2007) simulated the effect of deep tillage to overcome soil compaction on wheat productivity to quantify the potential benefits of deep tillage. These benefits ranged from positive to neutral to negative effects on yield, depending on soil type and seasonal rainfall. Tang *et al.* (2003) used the same soil hospitality factor as the basics to simulate the impact of various degrees of soil aluminum concentrations on root growth and subsequent grain yields in a low rainfall environment.

Salinity is a widespread soil constraint that can reduce crop growth and yield. Some salinity impact-routines, such as the function proposed by Van Genuchten (1987), have been used to relate water uptake to the average salt concentration in the root zone. For example, Dixit and Chen (2010) integrated the van Genuchten function into a spatially referenced water and nitrogen management model (WNMM) model (Li *et al.*, 2007) to understand the spatial yield variability because of salinity constraints. Other models consider the flow of water in the soil and use a mixing algorithm to simulate salt movements between soil layers. For example, this salinity algorithm has been included in APSIM to simulate the effects of irrigation water and chloride accumulation in soils (Snow *et al.*, 1999). Excess water or water-logging is another soil-related constraint that can limit crop growth. A simple water-logging routine has been included in the crop model APSIM-NWheat, which simulates the dynamics of a water table and its effects on root and crop growth (Asseng *et al.*, 1997).

Drainage

Drainage of water from the root zone occurs when the amount of rainfall is more than the soil can store. Drainage can be considered 'unproductive' water and causes dry-land salinity in some regions. Drainage is difficult to measure in the field and has spatial and temporal variability because of different soils and varying amounts of rainfall. Crop models are valuable to help quantify the potential of drainage across soils and regions (Asseng *et al.*, 2001b).

Nitrate Leaching

Groundwater pollution caused by excessive inorganic nitrogen (N) fertilization is a widespread environmental problem in many agricultural systems. N in the form of nitrate ($NO3^-$) is very mobile in the soil and can easily leach with moving water. Rainfall or irrigation can cause significant amounts of N leaching if large amounts of nitrate are present in the soil. N leaching can also cause soil acidification, another potential soil degradation that limits crop growth. As a consequence, regulators are attempting to restrict excess nitrate in soils. For example, the European Union (EU) Nitrates Directive (91/676/EEC) aims to preserve groundwater quality by promoting farming practices that increase N use efficiency of cropping systems (Basso *et al.*, 2010). Crop models have played a role in determining crop management and its impact on externalities, such as N leaching. For example, Asseng *et al.* (1998) used a crop model to show that on sandy soils and high rainfall, most of the initial soil N is lost to leaching before roots can take it up. Basso *et al.* (2012) used a crop model in a field study and showed that less N fertilizer can be used to reduce N leaching without causing reductions in economic return from the crop. Giola *et al.* (2012) quantified the nitrate leaching caused by mineral and organic fertilizer applications over 2 years of a maize-triticale rotation at a site in Italy with the SALUS model. The model showed nitrate leaching from slurry and manure was significantly reduced when applied without additional mineral N applications.

Soil Carbon

The amount of soil carbon and its dynamics play a crucial role in agricultural productivity and global climate stability. Numerous crop models that include soil carbon are currently available. These models differ in objectives, level of complexity, and relationship with other agricultural components. Most models present different fresh organic matter (metabolic litter: easily decomposable fresh residues; and structural litter: recalcitrant fresh residues such as lignin) and organic carbon pools. An active pool is based on material (sugars) with a mean residence time (MRT) <1 year. An intermediate pool is based on lignin and cell walls with a MRT of 30 years, and a resistant pool is formed mainly by inert material and stabilized microbial material. One of the most widely used soil carbon models, the CENTURY soil carbon model (Parton *et al.*, 1988), has been adapted for use in the DSSAT cropping system model (CSM) (Gijsman *et al.*, 2002). Senthilkumar *et al.* (2009) used the SALUS crop model to simulate soil carbon dynamics in a cropping system in Michigan under different tillage and fertilizer management strategies. The model predictions of soil C changes closely agreed with the observed results for the conventional tillage and no tillage fertilized treatments.

Breeding

Phenotypic Trait Expression

In the 1990s, crop models began to address the impact of phenotypic traits on cultivar performance and how trait values are gene based. White and Hoogenboom (1996) incorporated the effects of seven traits involving phenology, growth characteristics, and seed size for dry bean. Elings *et al.* (1997) used crop modeling to gain insight into how to increase maize yields in tropical environments. The authors concluded that yield was sink limited and could be improved by increasing the size of primary ears or by increasing plant density, which in turn increased the density of primary ears. The authors also concluded from the simulation analysis that yield can be increased under drought conditions by selecting for genotypes that have higher seed set.

Wilson *et al.* (1998) and Wu and Wilson (1998) simulated rice cultivar performance by incorporating primary phenotypic traits, which are described as being near invariant for a wide range of climatic and edaphic environments. A crop model was verified and validated across 13 crop data types for cultivars that exhibited a range of growth patterns. The authors proposed to use their model to identify which combinations of primary phenotypic traits to select to develop higher yielding cultivars. Wilson *et al.* (2000) presented simulation results supported by field data showing that rice yields can be drastically increased for the Texas Gulf Coast environment by selecting for genotypes that produce phytomers at a quicker rate and produce panicles at a slightly higher nodal position.

Genetics of Phenotypic Expressions

Hoogenboom and White (2003) categorized the degree to which different crop models incorporate genetic detail and concluded that most are at level three of a six-level scale. On the scale, level three means genetic differences are represented by cultivar-specific parameters, whereas level six means the generic model has no reference to species. Yin *et al.* (2003) combined crop modeling with quantitative trait locus (QTL) mapping. QTL mapping involves segments of DNA linked to the genes that underlie a crop phenotype. They did this by replacing measured input trait values with predictions from QTLs, and Messina *et al.* (2006) continued this in subsequent efforts. White *et al.* (2008) concluded that it is possible to use genetic data to estimate trait values, but that the estimates are not as accurate as those provide by directly measuring trait values and require more extensive genetic characterization. Chenu *et al.* (2009) studied the pleiotropic effects (a gene influences multiple phenotypic traits) on maize silk elongation. They illustrated the inability to interpret genetic control of yield by solely using additive effects of QTLs, but concluded that modeler/molecular biologist teams should use crop genotyping to improve the prediction of a cultivar's trait values.

This research suggests the current level of understanding of gene expression is not sufficient to accurately predict the majority of phenotypic traits from a cultivar's genotype or to allow accurate modeling.

Improvements in Cultivar Development

Although recent literature demonstrates the potential for using crop models to quantify the effects of phenotypic traits on cultivar performance, progress has been limited in using models to develop improved cultivars. Samonte *et al.* (2011) described progress with the Texas A&M marker- and model-assisted rice cultivar development program, where genotypes were selected based on two primary phenotypic traits and two secondary traits. The two primary traits were maximum mainstem node production rate and panicle node number, and the relatively easy to measure secondary traits were two primary phenotypic traits, potential leaf growth rate and maximum spikelets per panicle. This approach differs greatly from that of conventional inbred selection. In this approach, recombinant lines are selected based on primary phenotypic trait values and are not based primarily on yield. As a result, 22 (85%) of the 26 selected genotypes yielded more than the inbred control cultivar with the upper 5 (19%) producing an average of 23% greater yield. Consequently, the first rice cultivar was develop through marker- and model-assisted selection (**Figure 3**), which produced 7% greater yield than the best performing commercially available inbred cultivars (Tabien, personal communicaton, 2012).

Inbred breeding in the future will likely see the greatest initial strides in the use of model-assisted selection because cultivar selection programs for inbred genotypes are more straightforward than hybrid selection.

Figure 3 Panicles of rice cultivar 'Colorado' at the grain filling stage. Cultivar Colorado is a high-yielding semidwarf long-grain rice cultivar, and is the first rice cultivar developed using marker- and model-assisted selection. Colorado was developed by the Texas A&M AgriLife Research Center at Beaumont Texas (Photograph by R.E., Tabien).

Climate Change

Impact of Past Climate Trends

As the global climate has been changing and will continue to change (IPCC, 2007), crop models have played a key role in determining the impact of climate change in agriculture. A number of crop simulation studies have shown that past climate changes have affected cropping systems. For example, Ludwig *et al.* (2009) used a crop model to determine the impact of recent rainfall decline of up to 20% on crop yields and drainage. They showed that grain yields were not affected by rainfall decline, but drainage was significantly reduced. By using the model, they explained that limited soil water holding capacity and reductions of rainfall during the wettest part of the seasons were the reasons for these unexpected findings. Similarly, Liu *et al.* (2013) studied the effects of past climate change on crop phenology and production using a crop model for rice in China.

Impact of Future Climate Trends

Crop simulation models have been a key tool in assessing the impact of future climate change. A range of plausible projections (scenarios) of emissions from a number of general circulation model ensembles and various downscaling methods are usually employed together with single-crop models. Including these projections in crop models can help to assess possible impacts and explore management strategies to adapt to climate change. Many future climate change impact assessments have been carried out using crop models for specific locations (Semenov *et al.*, 1996), agricultural regions (Tao *et al.*, 2009), and at the global scale (Rosenzweig and Parry, 1994). Experts suggest including the uncertainty in crop models in such climate change assessments and multimodel applications. Including uncertainty ensures that crop models are used in a similar way to the multimodel approach in climate change science (Meehl *et al.*, 2007). The recently founded Agricultural Model Intercomparison and Improvement Project (AgMIP; www.agmip.org) is a major international collaborative effort to assess climate impacts on the agricultural sector. AgMIP incorporates state-of-the-art climate products as well as crop and agricultural trade model improvements in coordinated regional and global assessments of future climate impacts. Instead of using single-crop models, the project includes multiple models (**Figure 4**), scenarios, locations, crops, and participants to standardize climate change impact studies and define the uncertainty of impact assessments (Rosenzweig *et al.*, 2013).

Adaptation to Climate Change

As the global climate is changing, agriculture will need to adapt to the changes to maintain and improve crop production. Studies show that without adaptation, climate change may create considerable problems for agricultural production and communities in many regions of the world (Wall and Smit, 2005). Crop modeling has been used to determine the impact of climate change and to explore adaptation options (Luo *et al.*, 2009). These strategies included changes to sowing dates (Alexandrov *et al.*, 2002), irrigation (Chen *et al.*, 2012), nitrogen fertilizer input (Liu *et al.*, 2010), and cultivars (Butt *et al.*, 2005).

Mitigation

Agriculture can be of paramount importance for minimizing the impacts of climate change. Certain agricultural management practices allow for soil carbon sequestration, such as zero tillage and retaining residues on the soil surface, whereas others can help increase productivity and use less fertilizer. These practices will reduce greenhouse gas emissions such as CO_2 and N_2O, as these two gases are highly dependent on the level of soil organic carbon and the amount of nitrogen fertilizer added. Basso *et al.* (2012) demonstrated that through the use of crop modeling combined with precision agriculture technologies, the optimal amount of N fertilizer could be reduced, leading to lower N_2O emissions. In another study, a crop model was used to show that variable rate input (i.e., tillage, seeding, cultivars, fertilizer, irrigation, pesticides) can lower greenhouse gas emissions by more efficient use of products and energy reductions (Bertocco *et al.*, 2008). Also, crop models have helped increase yield by sequestering more carbon from the atmosphere (Basso and Ritchie, 2012).

Glossary

Animal husbandry The different aspects involved in raising animals in agricultural settings.
Cold chain The transport and storage of perishable products at appropriate cold temperatures to prolong the shelf life of the product.
Coprophagia Consumption of fecal matter; pigs are coprophagic.
Food safety The proper handling of food, preparation, and storage to avoid contamination that may cause illness to humans.
Food security The access of food, the availability, and the nutritional value of the food.
Goshala Protected shelter area for cattle, a sanctuary for animals due to their religious significance; for example, *goshalas* in India for cows, calves, and oxen.
Gray water Water contaminated with waste from household use that is recycled for other use such as irrigation and flushing toilets.
Production diseases Diseases of animals affecting the production capability; for example, mastitis affects milk yield.
Reportable diseases The occurrence of a disease requiring obligatory reporting due to the importance to human or animal health.
Zoonosis Diseases transmitted between animals and humans; the biological cycle may include one or more species and humans, humans could be an accident in the cycle.

Introduction

Slums are human settlements developing in peri- and urban areas. Often not recognized as part of planned urban environments, slums continue to grow in number and size around the world. There are now 800 million to a billion people living in slums, a large percent of the seven billion worldwide. Slums are difficult to define based on a single characteristic because they are not homogeneous within cities in a country or among countries; their unique milieu depends on the geographical location of the settlement, the socio-anthropological background of the dwellers, and the history of its development. Notwithstanding the sociocultural differences, slums have some common characteristics: poor housing, often illegitimately built on private or public land with poor drainage and unfit for agriculture; overcrowded conditions; limited access to potable water; poor sanitation and lack of sewage or waste removal; high numbers of domestic pets; and clandestine keeping of livestock.

Slums originate from the need of people for a place to live after displacement due to drought, famine, or wars, and migration from the countryside into the cities by the push of rural unemployment and the pull of urban opportunities. This migration from rural to urban areas populates informal settlements in the periphery of cities and towns in many countries (United Nations, 2011). Demographic information from slums is only as good as the reports governments make. Less than 100 countries report data on slum human population, and from those, 37 indicate they have more than 50% of the population living in slums. One country reported that 94% of the population lives in slum conditions (United Nations, 2007). In the 2013 census in India, 65 million people were identified as living in slums (Government of India, 2013), which is probably an underestimate.

In lesser developed countries, the increase in the urban population dating from the 1970s is parallel to the decrease of the rural population. Demographers expect that 60% of the world's population will live in urban areas by the year 2050 and 2 billion people will be living in slums (United Nations, 2011). In Africa, the population in urban areas increased sevenfold in 50 years. Population density in some slums has reached 200 000 people per square kilometer, as in Bangladesh (Huque, 2005). With one in every seven people living in a slum, ensuring sufficient food becomes a concern; slum livestock agriculture could be part of the solution to fulfill the nutritional needs of that many people (United Nations Human Settlements Programme, 2003).

Production of food in slums is clearly different from rural, peri-urban, or other types of urban agriculture developing in many industrial countries. Urban agriculture had been characterized as a decentralized supply system composed of small and scattered production units (Mougeot, 2000). There are other classifications of urban agriculture, only some of which include slum agriculture (Egbuna, 2008). Slum livestock keeping is especially difficult to classify. The lack of basic resources to maintain and exercise good agricultural practices coupled with unsanitary slaughter is likely to render slum livestock agricultural products unfit for human consumption. However, despite all the negatives, slum livestock agriculture is a means of securing food, earning income, and supporting livelihoods of slum dwellers. Slum agriculture benefits from a large market close at hand, low transportation costs, availability of production inputs, the ability to make use of waste foods and water, and low entry costs to setting up production (Food and Agriculture Organization, 2001).

Informal markets for real estate and goods develop in slums, including markets for processed and unprocessed animal products (Potsiou and Ioannidis, 2007). Peri-urban and urban

livestock agriculture is a complex and multifaceted activity developing in an environment often unfit for human habitation. Roaming chickens, pigs, and goats are a common sight in slums, and even cows and animals used for transportation or hauling such as donkeys and horses can be seen. In different regions of the world, different animal species are popular: goats and sheep are more common in Africa and Southeast Asia, and pigs are more common in Latin American slums. Food animals in slums are a public health concern due to their potential for transmitting zoonotic diseases, unsafe food products, the risk of physical injuries and traffic accidents, and environmental contamination. Animal products processed locally enter the general population food chain through peri-urban and urban food markets. Owing to the lack of a proper waste disposal, animal and human waste mixes in the streets with leftover water from household activities. Stagnant water and waste, garbage, and other contaminants develop a foul smell and attract vermin and insects. Untreated wastewater flows into local waterways and is drunk by roaming animals. This gray water is often used for urban vegetable or crop farming.

There are few estimates of the volume of animal or vegetable products originating from slums used to supplement the family diet or entering the food chain through peri-urban or urban markets. In Ghana, 95% of the lettuce consumed in Accra is produced in urban and peri-urban areas (Amoah *et al.*, 2007). In the Chimbote slum in Lima, Peru, where 400 000 people live, it has been estimated that there are 280 swine production units (Chimbotenlinea.com, 2014). That is approximately 25% of the households in the slum assuming there are four members per household.

Livestock Production in Slums

The Food and Agriculture Organization of the United Nations has conducted technical consultations and extensive studies on urban and peri-urban agriculture. Thirty percent of the meat and 70% of eggs produced in the world is associated with urban production (Food and Agriculture Organization, 1999). It is not clear if slum agriculture production is included in these estimates. Slum livestock keeping is typically smaller scale than the peri-urban and nonslum urban agriculture. However, slum agriculture has rarely been the focus of systematic evaluations and studies. The complexity of this type of slum livestock agriculture and its implications in the social and political arena is, however, getting recognition (International Livestock Research Institute, 2012; Lemma and Rao, 2013), and some evidence is emerging on scale and importance. In Maputo (1.2 million inhabitants), Mozambique, more than one in three households in urban areas raises livestock (International Livestock Research Institute, 2013). In Ibadan in southern Nigeria, one in three urban households kept livestock, whereas in Kaduna in northern Nigeria nearly half the households kept livestock (International Livestock Research Institute, 2013).

Species of Animals and Production and Scale

Livestock production in slums is typically small to medium scale and low technology. Chickens and pigs seem to be ubiquitous in Latin American slums, whereas goats and rabbits are favored in Africa and Southeast Asia. Cows are noticeable in India and Nepal where, for religious reasons, they cannot be slaughtered. Some animals in slums are allowed to roam and scavenge whereas others are confined in unsuitable small spaces shared with humans. The scale of this agricultural activity varies in type and size and it can range from subsistence to small- to medium-size commercial enterprises with hundreds of small animals. In more densely populated slums, fewer animals are kept and enterprises are likely to be small scale; where more land is available, livestock keeping is more common and on a larger scale (Box 1).

Smaller species: Chickens and rabbits

Chickens are animals most commonly raised in slums. One or two hens and one rooster roaming free with a few chicks is a common sight. It is not uncommon to find medium (10–30

Box 1 Livestock keeping in Dagoretti district, Nairobi, Kenya

Dagoretti District lies to the west of Nairobi city, 12 km from Nairobi city center. It is one of 8 urban districts in Nairobi and has around one-tenth of the total population. Most inhabitants live in tin-roofed timber houses with inadequate access to piped water, sanitation, and electricity. Unemployment (approximately 60%), human immunodeficiency virus-acquired immune deficiency syndrome, crime, and homelessness are persistent problems. Dagoretti was originally outside the city of Nairobi, but when the boundaries were extended in 1963, it became part of the city. Dagoretti district has both government and ancestral land. Some ancestral land has been sold to migrants, and government land has also been allocated to individuals. In some areas, squatters live on land temporarily leased out by landlords, a loose agreement, which can be revoked at any time. The population in the last available census was 240 509 up from 41 409 in 1969, a vivid illustration of the rapid growth of cities. Of the population, 42% are below 19 years of age, an age distribution that is also typical of developing countries.

A recent survey characterized livestock keeping in Dagoretti. More than half the households kept animals: in order of declining popularity: dogs (39%); poultry (39%); cats (37%); sheep and goats (14%); pigs (10%); and cattle (1%). A few households kept other animals including, rabbits, donkeys, doves, turkeys, ducks, and geese. Dogs were kept mainly for security, cats for vermin control, donkeys for work, geese for security and food production, and the other species were kept mainly for food production. In addition, cattle manure is a valuable by-product used for urban crop and vegetable production, and livestock are an easily liquidated asset that can be sold to meet urgent household needs or act as pledge enabling access to credit. Moreover, farmers report deriving social and psychological benefits from livestock keeping.

The study focused on dairy cattle kept by 1 in 80 households in Dagoretti. Farmers kept an average of three cattle. Nearly all households kept productive breeds, used artificial insemination, and zero grazing. Farms produced approximately 12 l of milk a day, and 88% of this was sold with the rest being consumed in the household. Most of the milk produced is sold in the community through informal markets. All sales of milk earn farmers in Dagoretti approximately US610 000 per year. Farmers reported that both demand and production are increasing.

chickens) to larger layer flocks (up to 100 chickens) in confined spaces. Chickens are the most versatile of poultry, given the value added of egg production and the worth of the animal, live or processed. In slums with limited electricity or where the cold chain is not available, chickens and eggs are a quick and easy source of protein and income generation. Chickens have an additional value because they are used in religious ceremonies and offerings (Alves *et al.*, 2009). The breeds of chickens vary from region to region and some commercial breeds are seen in slums. Scavenging chickens are fed in the morning with leftover food and possibly with added corn or poultry meal. During the day, chickens eat insects, garbage, and organic matter found in empty lots or by the side of the road. Housing is rudimentary and may consist of hay or rice husks arranged in cardboard or wooden boxes and placed off the ground for protection from dogs and predators mostly during the night. Raising chickens is considered an easy activity requiring minimal labor and is usually performed by women and children (Food and Agriculture Organization, 2001).

Backyard flocks requiring additional attention compete for space with humans and other animals and are more labor-intensive requiring feeding, watering, and pen cleaning. Noise levels and manure disposal become a problem with larger flocks and are a deterrent for keeping them in small and crowded spaces. Larger flocks are more common in peri-urban areas than slums, but broiler chickens keepers may have more than 100 birds, as in the case in the Mombasa slum in Bangladesh where a bird keeper is reported to have between 125 and 250 birds (Sabuni, 2010). Live chickens are transported in cages or burlap bags to nearby food markets. These markets are located at walking distance from the dwelling where the animals are raised, although sometimes birds are transported in cages on top of buses or trucks to other urban markets. Chickens are sold live or slaughtered on site at the buyer´s request. Eggs have a longer shelf life (lasting 3–4 weeks without refrigeration depending on environmental conditions) than poultry meat. Eggs are wrapped in newspaper and kept in the shade to prolong their shelf life. They may be sold to neighbors in small numbers, as needed, for income generation or in larger numbers at markets. Other poultry kept in slums include turkeys, geese, doves, pigeons, quail, and guinea fowl.

Rabbits are gaining popularity in slums in Africa. They can be kept in small spaces in crates, either individually or in small groups. Rabbit crates are easy to build and can be kept stacked up against each other or leaned against a wall to occupy less space. These animals require more attention than scavenging or backyard flocks of chickens for feeding, watering, and cage cleaning. However, it is a profitable and uncomplicated business as evidenced by the number of rabbits a person can keep. One resident in the Kahawa Soweto slum in Nairobi has more than 400 rabbits in a shed (Kelto, 2013). Rabbits are fed greens collected locally and supplemented with vegetable leftover from markets or pelleted food. This is a small species that can reach to 4 kg of weight and can easily be processed locally as chickens for sale or family consumption. In a space of 30×40 feet, slum residents can raise more than 500 rabbits of different breeds. More unusual animals are also kept: a survey in Nigeria reported snails, grass cutters, and antelope among a total of 14 species kept.

Monogastrics: Pigs

Pigs adapt easily to urban conditions. One sow can produce 6–12 piglets twice or three times a year if their reproductive cycle is timed properly (pregnancy lasts 3 months, 3 weeks, and 3 days). Selling the piglets before birth is not uncommon at certain times of the year for events or festivities where pork is commonly consumed. Pigs are considered a form of saving account because piglets can be sold for cash or given in exchange for the boar´s service (the piggy bank). Boars can grow tusks and become very large and aggressive, requiring confinement to protect people and other animals. This is why fewer people keep boars compared to sows. Rearing of pigs in slums in small numbers (one to five) is often done by women and larger herds by men (Food and Agriculture Organization, 2001). Piglets are easy to manage because they can roam during the day searching for food and come back to their home space at night. They can also be tethered and kept close to the dwelling, or housed in makeshift pens behind or in the confines of the human dwelling.

Nowadays pigs are ubiquitous to slums in Latin America and present even in countries with Muslim and Hindu population such as India and Nepal (Rajshekhar, 2004). It is difficult to establish the genetics of pigs commonly reared in slums. These are smaller and more adaptable to the local conditions than large commercial breeds. Pigs revert to wild type very quickly and grow hair and tusks adapting to the environment. However, pigs kept in confined spaces in and small numbers are usually larger commercial breeds requiring more attention and feeding.

The creole pig from Haiti was an example of a small hairy dark pig well adapted to the environment, eating garbage and fallen rotten fruit. They had sociocultural value and were considered to have an important role in recycling waste. Issues associated with swine fever in the late 1970s and early 1980s prompted the United States Department of Agriculture and other international organizations to develop and conduct an eradication program. The sociocultural value of these animals was not clearly understood. People were given large commercial breeds as substitutes for the creole pig and asked to pen the pigs. The larger breeds had to be fed and cared for and were not allowed to roam, which resulted in detrimental conditions of the environment in which people lived (Ebert, 1985).

Ruminants: Goats and cattle

Goats are adaptable to urban environments. They are known for eating almost anything, including bark from trees and shrubbery, garbage from streets and land fields, or clothes hanging to dry. These animals require attention, given their inquisitive nature and destructive eating habits. Usually people keep a couple of female goats for their milk with the offspring. In slums close to peri-urban areas people keep the goats in pens or house patios during the night and walk them to pasture at different locations during the day. In the urban environment, and in particular in slums, goats roam the streets in search of food, and it is common to see them searching for food with pigs (Diogo *et al.*, 2010). Goats can decimate green areas very quickly, causing damage to vegetables growing by the side of the roads or public open spaces. They require more attention than chickens or pigs and they need shelter from the

rain. Goats' milk is nutritious and can be easily transformed into yogurt and cheese to extend the shelf life of an otherwise perishable product. In some large slums such as in Delhi, India, slum goats' sightings have become a tourist attraction and are offered as part of city tours (News.com.au, 2013).

Mixed *Bos taurus taurus* and *Bos taurus indicus* cattle are let free in search of food or water or walked to pasture in the mornings and brought back at night. In countries with a predominantly Hindu population cows are sacred and only the milk is consumed. Oxens are mainly kept for draught power; they are used for plowing and also transport. Owing to religious reasons female cattle cannot be disposed of after their productive lives have ended. Older unproductive animals may be abandoned and may die of diseases, hunger, intoxication from garbage, or get involved in traffic accidents. There are also many *goshalas* in India where abandoned cattle are looked after. Milk is a valued product that contributes to food security in slums. But it is perishable and has to be consumed quickly or transformed into a variety of cheeses, yogurt, or sour milk. Naturally fermented sour milk is popular in East and West Africa; fermenting also removes lactose, which makes it easier to digest for populations that do not have lactase enzymes persisting in adulthood.

Tending larger animals is time consuming and may involve walking long distances to find a place to feed away from the city or to cut grass that can be brought back to the animal. This is easier to do when the slum is located in the periphery of a city compared to an urban-area slum. Often cattle are confined to a small space or their mobility may be limited by tethering them close to the dwelling. Studies of peri-urban dairying in East Africa found that nearly all cattle were 'zero grazed,' that is, kept inside all the time (**Figure 2**).

Cow dung in India is also a valuable fuel: it is collected, reshaped into cake-like forms, and dried. In India and elsewhere cattle dung is also used as a building material mixed with mud and other substances. Livestock value is more than monetary; it is a symbol of social status and social identity both individually and collective (Comaroff and Comaroff, 1990). The value of livestock and the production parameters used elsewhere (such as in the industrial countries) need to be revaluated because a cow or goat whose production is low may still be providing useful services (Dutta, 2003).

Production Challenges in Slums

In slums, an intricate relationship exists between poverty, food security, livestock keeping, and the environment. Enforcing livestock regulations becomes a difficult task when animal ownership is clandestine. In many countries regulations cover animal health and welfare issues, the disposal of dead animals, slaughter procedures, and environmental contamination, but in practice they are not enforced in slums. In other cases, regulations are used for 'rent-seeking' by authorities: that is police or other officials will confiscate animals and not give them back unless a bribe is paid. Keeping animals in cities undoubtedly creates environmental problems. For example, in Kisumu, Kenya, keeping animals is illegal. The city has six slums and enforcing animal farming law is a challenge. The dung of the animals becomes a problem when the rain washes it and contaminates the city water supply. The city lacks the infrastructure to recycle the dung and 75% of it is not utilized (New Agriculturist, 2006). Yet the Draconian response of banning livestock from cities may not be the most appropriate. In Kampala, Uganda, a process lasting several years has recently led to new City Ordinances that seek to support urban agriculture as an important economic activity, while regulating against the potential adverse effects.

Burden of Disease

Animals of the same or different species in slums are in proximity with each other and with humans. Contagious diseases can spread rapidly under these conditions. Additionally, slum-raised animals suffer from malnutrition coupled with an adverse environment that makes them more susceptible to disease or injury (Food and Agriculture Organizations, 2011). Some problems are associated with animals living in areas with poor waste disposal. Pigs and goats eat plastic bags and these are common findings at slaughter or necropsy. The bags fill the stomachs impeding food digestion and nutrient absorption. Rwanda banned nonbiodegradable plastic bags in 2008, an excellent example for other African countries where plastic waste is ubiquitous.

The health of animals in slums requires attention, but estimating disease and its impact is difficult. Both zoonotic (diseases transmitted from animals to people) and nonzoonotic animal diseases need to be considered. Reportable, zoonotic, and production diseases are discussed elsewhere in this encyclopedia. Some of these diseases are of national public health interest or are of international trade importance requiring immediate reporting through specific official public health channels and to the World Organisation for Animal Health, one of the three sisters of the World Trade Organization. Reportable diseases of animals are those with the potential to cause epidemics or pandemics that cause serious disease in people, as is the case of the severe acute respiratory syndrome known as SARS, the H5N1 (pathogenic avian), and H1N1 influenza virus (known as swine influenza) (Gauthier-Clerc *et al.*, 2007; Girad *et al.*, 2010). Public health resources and market inspections are deployed for some of these diseases, but control is often ineffective in poor countries. Determining the public health penetration of these programs in slums has been highlighted as a need (Unger and Riley, 2007). Risk communication in a crisis situation involving the livestock population in a slum may require additional resources and targeted programming. The lack of information of the size and location of the avian and swine population may impede the progress of disease control measures. Public awareness programs or the application of rigid standards for disease control without consideration of the sociocultural and economic value of the animals for people may also decrease compliance (**Box 2**). References to the 1920 flu pandemic are always brought to light in the media as the possible serious consequences of disease spread and death. However, public health crisis response is different today and includes emergency and disaster preparedness, first responders training programs, and damage mitigation and relief. Nonetheless robust economic estimates by the World Bank suggest that the

Box 2 The unanticipated effects of disease control

A pandemic of H1N1 influenza was declared in 2009. This disease originated in pigs but subsequently was maintained entirely by human to human transmission. In response to the pandemic, the government of Egypt ordered all of the country's pigs to be slaughtered. Because humans can only get the new flu from other humans this was not effective as a control response. It also had far-reaching and unintended consequences on the cities' waste management. Cairo's 30 000 garbage collectors used to feed the city's organic waste to pigs and their livelihood became endangered while the streets of the capital filled up with trash.

Figure 1 Cysticercus in pig muscle, Bolivia.

cost of an epidemic originating in animals could be a trillion dollars (World Bank, 2012).

There are approximately 1000 zoonoses or diseases transmitted from animals to humans. Disease transmission may be direct through contact with infected animals or its fluids, or through contaminated animal products, water, or objects contaminated with infectious material (Center for Disease Control and Prevention, CDC 24/7, 2011). Especially important for poor countries are the so-called neglected zoonoses often associated with poverty, poor hygiene, and poor understanding of disease transmission. The rest of the article discusses some neglected zoonoses that are known or likely to be a problem in slums.

Brucella melitensis, the cause of brucellosis, is very pathogenic to humans (Center for Disease Control and Prevention, 2012). It is transmitted from goats and sheep to humans through direct or indirect contact. Unpasteurized milk or contact with body fluids of infected animals are considered the most common transmission routes. There are other brucellae affecting swine, cattle, and dogs, but *melitensis* is associated with the more severe forms of the disease. Flaying and skinning sheep by blowing air through a cut in the skin exposes people to body fluids and inhalation of bacteria from infected animal, and hence is not recommended.

Cysticercosis is a disease caused by the larval stage of the tapeworm *Taenia solium*. The disease is sometimes wrongly known as the 'the pig tapeworm,' but humans are the definitive host for the adult form of the parasite, not the pig. The adult parasite releases segments daily containing thousands of eggs into the gut. These eggs pass into the environment with the feces. Humans and pigs become infected and develop cysticercosis by ingesting the parasite eggs. Pigs are coprophagic and human defecation in open spaces is one of the main forms of transmission of the disease from humans to pigs. When eaten by pigs, the eggs develop into cysts within the pig (**Figure 1**). If people eat meat containing viable cysts these can develop to tapeworms in the human host, thus completing its cycle. Human to human transmission occurs when people harboring the parasite contaminate food due to poor hand hygiene (Garcia *et al.*, 2001; Carrique-Mas *et al.*, 2001). Autoinfection can also occur following improper hand washing after a bowel movement. After humans consume eggs, cysts start to develop in any organ of the body, including the brain. When cysts develop in the brain, the disease is known as neurocysticercosis. It is considered as one of the most common infestations of the brain in humans. The main manifestation of the disease is epilepsy (Garcia *et al.*, 2001). Studies from a slum in India revealed that 25.5% of people in the studied sample who had active epilepsy had antibodies to *T. solium* (Singh *et al.*, 2012). Cysticercosis in pigs may reach 30% prevalence or more in some countries where pigs are allowed to roam and human defecation is done in the open (Carrique-Mas *et al.*, 2001; Fleury *et al.*, 2012; Flisser *et al.*, 2003). Even with low human taeniasis in the order of 1–2%, the prevalence of cysticercosis in pigs can be high. This is mainly due to the fact that only adult parasite can live in the intestine of the host for years and release thousands of eggs into the environment.

Hepatitis E virus is an enteric disease transmitted from different species of animals including pigs to humans; it can be transmitted between humans through contaminated water and food. The seroprevalence in the human population unexposed to swine is 2% whereas the seroprevalence in swine workers or other swine-exposed populations is 10% (Whithers *et al.*, 2002). Data from a study of a pediatric population in Karachi with access to municipal piped water and nonflush toilets in a slum in India showed a high seroprevalence for hepatitis E virus (Jafri *et al.*, 2013). The exposure to hepatitis E virus seems lower than hepatitis A (Mohanavalli *et al.*, 2003). Hepatitis E is a disease that can cause severe gastrointestinal symptoms and has been associated with high death rates of pregnant women in lesser developed countries. In some peri-urban farms pigs are raised close to ponds where fish are kept. The pig feces are washed down to the ponds for the fish to eat. The virus seems to be ubiquitous in swine populations and undistinguishable even in samples from different countries. This was the case in hepatitis E study in two farming communities (not slum conditions), in North Carolina and Costa Rica (Whithers *et al.*, 2002; Kase *et al.*, 2008). Hepatitis E is a zoonosis, but the importance of animals in its maintenance and transmission has not been fully established.

Figure 2 Zero grazed cattle, Kenya.

Cryptosporidium is associated with cattle and causes diarrheal disease in humans and cattle. Although extensively studied in developed countries, it has not been diagnosed until recently in slums. Surveyed households in the Nairobi´s Dagoretti district, Kenya, determined the extent of cattle keeping and the prevalence of cryptosporidiosis. With a prevalence of 20% in urban cattle, this parasite could be a major contaminant of water sources and disease that needs further consideration (International Livestock Research Institute, 2012) (**Figure 2**).

Antibiotics and other veterinary drugs administered to animals without proper veterinary supervision can have direct and indirect consequences for human health. After administration of an antibiotic there is a period of time when the animal product should not be consumed. This period known as the withdrawal period is to allow the drug in question to clear the animal's system because it may have harmful health effects if consumed by people who are allergic or sensitive to the drug. For example, Clenbuterol is commonly used as a growth promoter (often illegally), and several outbreaks of illness have occurred when people consume livestock products from animals treated with Clenbueterol. Of potentially greater importance than sickness as the result of consumption of residues is the risk of bacteria developing resistance to antibiotics because of their use in agriculture. As a result of these concerns, many countries require that antibiotics and some other animal health drugs should only be prescribed by veterinarians. However, this is not practicable in most slums. Veterinary services may be out of reach for many people in slums either because of distance or cost. In some cases, livestock owners may visit a veterinary office and explain the symptoms of the disease to the veterinarian, but without proper examination of the animal and the information received, the medicines may not be appropriately prescribed. The livestock owner may not fully understand how to administer the medicines and use a single dose of a medicament keeping the rest in case the animal does not improve. Getting advice from another family member or neighbors, purchasing a single dose of an antibiotic from a street vendor, or using leftover medicines from a previous case is not uncommon. Veterinary services are often expensive and out of reach of the poor (Ahuja *et al.*, 2003).

In addition, farmers may use drugs for nonhealth purposes. In Khartoum, the practice of adding antibiotic to milk to preserve it was reported, and this could have health consequences such as allergy in the people ingesting the product (Hassabo *et al.*, 2012). In China, melamine was added to milk so that it would appear to have higher protein levels. This lead to one of the largest food safety events of recent years resulting in the death of six infants; the children died from kidney stones and thousands were hospitalized as a result of drinking the contaminated milk (Wei and Liu, 2012).

Markets

Slum agriculture and associated markets are part of the informal sector of the economy. It is a business model based on necessity, mostly home-based, and often clandestine. When there is no proper access to water and refrigeration, meat and eggs must be consumed rapidly, processed, and sold close to the place of origin. Markets in slums are public places where vendors congregate. Products may also be sold by hawkers moving from door-to-door or as requested. In many cities in developing countries milk is sold in this way. It is not uncommon to sell products from homes through modified window sills, from makeshift sale racks in corridors between houses, or on top of blankets or plastic sheets in the floor in open spaces. Slum dwellers acquire knowledge of who produces and sell different items. Prices vary based on perceived notions of quality, hygiene, or availability. The exchange of money is not always the norm for payment and people engage in bartering or exchanging products for services. Agricultural markets in slums differ from municipal markets where there is an operational legal framework and the state is responsible for the enforcement of public health and food safety regulations. However, the great majority of food sold in municipal markets lack any structured sanitary inspection. This does not mean that the markets in slums lack internal form of self-regulation, they have a *sui generis* operational business model. Although these markets are outside the purview of state regulation and disease control and preventative measures, the prevailing food-safety actions are based on accepted cultural norms. These norms are developed by the people who live, sell, and purchase products under these conditions or based on religious beliefs or restrictions (Rheinländer, 2006).

The number, identification of species, and location and ownership of animals in a slum is not usually performed. The lack of census data and owner identification poses a challenge for the implementation of national disease control or eradication programs. Required reporting of diseases and animal or product traceability to origin may be impossible in case of a food-related outbreak. This is contrary to the application of the Sanitary and Phtyo-Sanitary Measures of the World Trade Organization. Most countries agree to adhere to these measures when they join the World Trade Organization. Conducting an animal census in a slum is challenging but without knowing how many animals there are, vaccine campaigns or eradication programs cannot be conducted. However, the legally ambiguous position of livestock in slums mean owners are reluctant to incur official notice.

Slaughter

The inspection of animal facilities and product transformation industries destined for human consumption is highly regulated. Although in many developing countries animals must be processed in municipal slaughterhouses, at home and clandestine slaughter are common. In Bolivia, some of the municipal slaughterhouses are rudimentary and managed by the local communities. The official veterinarian is allowed to inspect the animals preslaughter and outside the facility. The inspection concerns mostly reportable diseases of national importance. Inside the slaughterhouse, skilled butchers castrate male pigs, and these and other animals bleed on the floor as part of the exsanguination process. Once the internal organs are removed the carcass is hung on a wall hook and employees rub the pigs´ canal with a rag. The same rag and water stored in a bucket is used to wash several carcasses. An inquiry into the practice revealed the employees neither understood why they were doing the cleaning nor how it was supposed to be done (Correa *et al.*, 2003). In Ibadan, Nigeria facilities are even less developed. Approximately 250–300 cattle are slaughtered daily; more are slaughtered on weekends, and fewer during Muslim holidays. Cattle are kept in pens, then moved to the slaughter slab. They are tied down at the slab and killed by cutting the throat. The dead cattle are then dragged on the ground to the abattoir area. This is simply a shed with a concrete floor and open sides. Removal of the intestines and quartering is done on the floor. Portions of the carcass are then carried to the adjacent butchers' stalls where they are sold. The abattoir is under municipal management and officers collect tax and tariffs on each cow amounting to US$1 per animal. The role of environmental sanitary officers is to inspect slaughter slabs and the general environment and ensure the area is clean. However, the filthy conditions of the market witness the challenges they face in carrying out their work. The veterinary department is supposed to check animals before slaughtering and inspect meat after slaughter, but many animals escape inspection, and even when problems are found veterinarians find it difficult to ensure condemned meat is discarded. Most butchers kill only one animal a day, and if this is condemned by veterinarians as unfit for human consumption they lose their entire day's earnings. Hence, they strongly resist attempts to condemn meat (Grace *et al.*, 2012).

Slaughter practices are probably clearly specified in pertinent regulations, but without oversight or evaluation by competent authorities, wrongly learned and applied practices may never be corrected. New employees learn from other employees and the practice is passed down, transformed, and perpetuated. The 'Trichina inspectors' in livestock markets in Bolivia are lay people trained by other people to inspect the tongue of pigs in order to detect cysts associated with cysticercosis. Trichina is a different parasite and the tongue inspection is not associated with this parasite, but *T. solium*. The wrong parasite reference has prevailed and the practice continues unchecked for efficiency in preslaughter diagnosis of cysticercosis in pigs. In Ecuador´s countryside, a traveling butcher works at the community slaughterhouses at scheduled days and times of the week and processes the carcasses of mainly large species at the municipal facility. This is a trained person who can condemn carcasses from sick animals and has an important food safety role. However, the most predominant form of slaughter in slums is the one done at home, in the streets, between or behind buildings. Usually for smaller species the head is removed using a sharp knife or axe against a hard surface like a piece of wood or the stump of a tree. The internal organs are removed swiftly; sometimes the esophagus and the rectum are tied to avoid intestinal content spillage and contamination. Animals processed in this manner are not properly exsanguinated. Raw offal may attract dogs and vermin. The meat, without refrigeration must be consumed immediately or it is left to dry on racks. Meat maybe carried to markets in small carts, buckets, or burlap bags and sold in small pieces or cut by the client´s request. The meat is not inspected when sold in the slums to neighbors or at smaller slum markets. In Nepal, animal parts are sold with other identifiable body parts like a hoof or horns in order to guarantee that the species being sold is the actual species. In many cases the meat is covered in turmeric, reported to be done to decrease contamination (oral tradition reported to authors by street vendors). Interestingly, homeopathy studies suggest that turmeric can help combat bacterial infections (Krup *et al.*, 2013; Vasavda *et al.*, 2013).

Conclusions

Slum livestock agriculture interweaves its existence with the geographic location and culture of the population. People take advantage of their new environment and recreate a way of living based on their upbringing, including raising and processing livestock. The main motivations for this activity are family subsistence, income generation, and social status. Slum livestock agriculture activities range from subsistence to semicommercial production. It plays a role in the livelihood of millions of people providing animal protein and generating income. However, it lacks technical sophistication and typically operates outside regulatory purview, and its practice overlooked and tolerated by local authorities. Animals pose a risk to human health and other animals, are a public nuisance, and contribute to the waste accumulating on streets and the run off contaminating the environment and water sources. Livestock products, raw or processed are sold in street markets and may enter the urban food chain. Animal ownership is difficult to establish in slums and livestock population difficult to determine. Under these circumstances, veterinary services and disease-control programs may be hard to implement. Good hygiene, good manufacturing practices, and animal slaughter inspection turn into an impossible task to implement and enforce. Disaster and white-coat diplomacy practices combined with information and communication technologies should be considered in the planning and implementation of public awareness and outreach programs (Lemery, 2010; Lin and Heffernan, 2010).

The elimination of the slums is not feasible. The magnitude of the animal population in slums is unknown, but its food security importance is getting recognition from public and private organizations. There is a need for a community-led approach in collaboration with private and public institutions, academic, international, and nongovernmental organizations to find sustainable solutions.

Small Ruminants in Smallholder Integrated Production Systems

JM Turk, U.S. Agency for International Development, Washington, DC, USA

Published by Elsevier Inc.

Glossary

Agropastoralists Producers who practice sedentary farming as well as temporary migration with livestock.
Caprinae Of or relating to goats.
Fat-tail or fat-rump sheep Domestic breeds of sheep found in North Africa, the Middle East, East and Central Asia; fat stored in the rump and tail is reserve source of energy during periods of sheeps nutritional stress; also used as food for humans.
Hair sheep Breeds found in hot, arid regions; hair fibers outnumber amount of wool fiber, resulting in shorter and smoother hair coat.
Mitochondrial deoxyribonucleic acid (mtDNA) The genetic material (DNA) contained cell structures important for creating energy; mtDNA is inherited only from females.
Pastoralism Pastoralists migrate in set patterns taking with them their flocks as well as family members.
Phylogenetic Relating to the development or evolution of a particular group of organisms.
Phylogeographic Relating to study of the processes controlling geographic distribution of lineages by constructing the genealogies of populations and genetics.
Urial Subspecies of wild sheep; most notable feature is the enormous curling horns on the rams.
Zoonotic diseases Diseases that can be passed from humans to animals and vice versa; tuberculosis is an example.

Origins of Small Ruminants

Evolution and Genetic Diversity

Studies of the earliest known existence of sheep and goats are based on Eurasian fossils 15–18 million years ago. During the late Miocene period, Caprinae evolved rapidly. It is one of the bovid subfamilies and species within it can be found across most of the world. Owing to its evolution in Eurasian mountainous regions, Caprinae species can tolerate temperature extremes occurring in such ecoregions (Estes, 1991; Hernandez-Fernandez and Vrba, 2005; Vrba and Schaller, 2000).

Lines of descent and ancestries between wild and domestic goats are clearer than those between wild and domestic sheep. Mitochondrial deoxyribonucleic acid (mtDNA) research has been used to track the domestication of both species. Such studies have revealed differences between diverse wild goat species and domesticated ones. Because there is no mtDNA recombination in females, genetic studies of samples revealed three ancestral lines with each having one set of chromosomes different from the other. Using these studies, researchers deduced that female Bezoar goats, the major contributor of modern goats, were captured during three separate times in three geographically separate locations, each one contributing to the formation of the early domestic populations. Even after thousands of years of interbreeding, mtDNA sequences from diverse wild species remain phylogenetically distinct (MacHugh and Bradley, 2001; Luikart *et al.*, 2001). Further research concluded that there are six lineages in Europe and Asia (Sardina *et al.*, 2006).

Where wild and domestic sheep are located within the same region, they can also interbreed, but unlike goats, sheep usually do not revert to a feral state. Moreover, unlike goats, researchers have not yet defined a precise lineage from wild to domestic sheep (Hiendleder *et al.*, 2002), although three major and distinct lineages were defined by DNA and mtDNA studies using European, African, and Asian domestic sheep (Pedrosa *et al.*, 2005).

Lineages were classified as Type A (Asian), Type B (European), and Type C (from modern sheep of Turkey or China). Another study determined that a Bronze Age sheep in China was Type B, leading researchers to conclude that it may have been introduced sometime in the fifth millennium (Guo *et al.*, 2005).

Scientists believe that these lineages descended from a different wild species of the genus *Ovis* (*Ovis gmelini* spp.) in the Fertile Crescent. This genus is highly polymorphic and includes several Eurasian wild sheep that may be ancestors of domestic breeds. There are several hypotheses about domestic sheep descending from wild ancestors. Origins include the European and Western Asian mouflon, the Asian urial, and the Asian argali. Asiatic mouflon continue to live in Asia Minor and Southern Iran, whereas European mouflon can be found on the Mediterranean islands of Sardinia and Corsica.

Although the urial had been considered to be the progenitor of the majority of current domestic sheep breeds, including the hair sheep of Africa and Asia, domestic sheep of India and the Far East are more closely related to the argali; both urial and argali were found to differ from other *Ovis* species in their number of chromosomes. This conflicts with the hypothesis of direct relationships, and further phylogenetic studies confirmed the absence of such evidence (Hiendleder *et al.*, 2002). In addition, more research showed major differences between the genetics leading to two possible explanations. One is the possibility that a heretofore unknown species or subspecies of wild sheep influenced the subsequent evolution of domestic breeds (Hiendleder *et al.*, 2007). Another conjecture relates domestic sheep breeds with multiple captures of wild mouflon over time (Meadows *et al.*, 2007).

 doi:10.1016/B978-0-444-52512-3.00160-1

Phylogenetic studies have led researchers to conclude that the Asiatic (*Ovis orientalis*) species of mouflon is the progenitor of *Ovis aries*. The original geographic range of wild sheep is the Middle East or Central or Western Asia (Williams). This has led to the theory that the European mouflon could be one of the ancient sheep breeds that reverted to the feral state, rather than a wild sheep that became domesticated (Ensminger and Parker, 1986). Past literature often cites the mouflon as the ancestor.

Climate, specifically temperature and level of precipitation, most likely influenced the regions where small ruminants evolved. In comparison with sheep, goats are more adapted to a harsher environment with conditions of greater aridity, lower quality forages, and less water availability.

History of Domestication

The earliest known domestication of small ruminants occurred in the Near East approximately 11 000 years ago during the Neolithic era (Zeder, 2008), although it is posited that some domestication began before this period based on archeological findings in different locations. Evidence of animal domestication dates to the last glacial period when humans began to practice settled agriculture, including animal production for meat and milk. Sheep are reputedly the first species to be domesticated for meat consumption.

Researchers conclude that during the early Neolithic period, when animal domestication emerged as an agricultural practice, there were different animal management strategies specific to geographic and sociocultural practices. Zoo archeological analyses of ancient caprine bones and teeth have been used to differentiate animals that were domesticated versus those of wild animals that might have been hunted (Arbuckle, 2008). Goats can revert to feral conditions if the chance permits, which provides a way to document genetic changes.

As human populations expanded, people began to migrate, taking livestock with them westward from Mesopotamia (the Fertile Crescent) into Eurasia. Tracing the routes from the Neolithic period when the earliest evidence arises, human migration flowed into Europe along two major routes – the Mediterranean and the Danubian (Hiendleder *et al.*, 2007).

Sheep

Archeological, genetic, and phylogeographic research provide evidence that most sheep domestication occurred approximately 10 500 years ago in Western Asia and that the species most likely was domesticated three separate times in the Fertile Crescent (Western Iran and Turkey) – in Syria and Iraq. It has been posited that dogs, the first animals to be domesticated, most likely factored into the sheep domestication process. Ancestral species of wild sheep can be found extending from China to Western Europe and by 3500 BC several breeds had been established in ancient Mesopotamia and Egypt (Budiansky, 1999).

After domestication in Western Asia, humans migrated with sheep through the Sinai into Northern Africa. Artifacts show that sheep were kept in ancient Egyptian society seven to eight thousand years ago (Blench and MacDonald, 1999). However, different environments between North and South interrupted or prevented the gene flow.

The dispersal across Eurasia and Africa happened by separate migratory paths. The first migration period included the mouflon and other primitive breeds, whereas the second migration period included animals with more productive traits. It is most likely that these sheep shaped the majority of current breeds (Chessa *et al.*, 2009). However, between the early and the late Bronze Age periods (3000–1200 BC), sheep breeds evolved and spread through the Western Asian region (Ensminger and Parker, 1986). Four ancestral species of wild sheep have been identified. They are: the mouflon of Europe, the Middle East (Asia Minor), and Western Iran; the urial of Western Asia and Afghanistan; the argali of Central Asia; and the bighorn of Northern Asia and North America (Pereira *et al.*, 2009).

As sheep became more domesticated and raised under containment, morphological changes occurred; body size decreased, females lacked horns, and there were larger percentages of young animals indicating planned breeding. The characteristics of wild species, such as lack of aggression and high reproduction rates, were considered of merit (Budiansky, 1999). Economically important traits, such as wool type and milk production, became selection factors. Selection for wool might have begun approximately 6000 BC (Ensminger and Parker, 1986; Weaver, 2005) according to archeological evidence from statues found at sites in Iran (Hyams, 1972), although there is a lack of evidence that wool was used for clothing at that early date (Smith *et al.*, 1997).

Archeological sites with early evidence for sheep domestication include Iran (Ali Kosh, Tepe Sarab, and Ganj Dareh, which is one of the earliest settlements in the Middle East), Iraq (Shanidar, Zawi Chemi Shanidar, and Jarmo), Turkey (Cayonu, Asikli Hoyuk, and Catalhoyuk, which is one of the oldest civilizations on record), and China (Dashanqian).

Goats

The earliest evidence of goat domestication is recorded at 10 000–11 000 years ago. They were adapted from a wild species, *Capra aegargus*, by Neolithic farmers. Like sheep, they were valued for milk, meat, hair, bone, and sinew for clothing as well as manure used for fuel. Goat remains have been found at archeological sites in Western Asia, such as Palestine (Jericho), Russia (Choga), Turkmenistan (Djeitun), and Turkey (Cayonu), which allows domestication of the goats to be dated at between 6000 and 7000 BC.

Unlike sheep, tracing the lineage of goats by mtDNA research has been more definite. Recent research has proposed that all current goat breeds can be traced to a small number of wild animals and then domesticated in two primary regions – Turkey's Euphrates River valley during 11 000 before present (bp) and Iran's Zagros Mountains during 10 000 bp (Zeder and Hesse, 2000). Other domestication sites include Pakistan's Indus Basin (9000 bp), Turkey (Cayonu – 8500–8000 BC), Syria (8000–7400 BC), Israel (Jericho – 7500 BC), and Jordan (Ain Ghazal – 7600–7500 BC) (Fernández *et al.*, 2006).

Goats were reportedly introduced into Northern Africa with human migration from the Near East, although questions arose over time regarding their origins. To genetically characterize the indigenous goat population, one study combined

mtDNA and Y chromosome loci from a population on the northwestern fringe. Sequence analyses coupled with 2000 published mtDNA sequences showed a striking level of maternal and paternal lineage diversity. Further studies concluded that there was a strong genetic relationship between Northwest African and Near Eastern goat populations (Pereira *et al.*, 2009). Crossbreeding over time has resulted in several hundred goat breeds today ranging from high-altitude mountains to arid and semiarid deserts.

Animal Population Densities

Based on the FAO's Statistical database (United Nations, 2010), the total number of small ruminants globally equaled 1 987 453 552. Of this total, sheep numbered 1 077 762 456 and goats numbered 909 691 096. The Asian region as a whole contained 50% of the world total. Of the 50% of the world total, 59% were goats and 42% were sheep. Within Asia, the subregion of Southern Asia had the highest percentage of animals (24%), of which 33.5% were goats and 16% were sheep. Africa held 31% of the world total (34% goats and 28% sheep) and within Africa, the subregion of Western Africa had 10.9% of total small ruminants, of which 8.6% were sheep followed by Northern Africa subregion with total of 8.6% small ruminants, of which 10% were sheep. Goats predominated in three of five regions in both Asia and Africa where the mixed crop–livestock production system prevails. The following list delineates total numbers and percentages.

World – 1 987 453 552 total small ruminants
- Sheep = 1 077 762 456 (54% of total)
- Goats = 909 691 096 (46% of total)

Asia – 994 069 195 (50% of world total)
- Sheep = 454 703 708 (42% of world total sheep)
- Goats = 539 365 487 (59% of world total goats)

Eastern Asia – 317 086 887 (16% of world total)
- Sheep = 148 682 613 (13.8%)
- Goats = 168 404 274 (18.5%)

Southern Asia – 477 368 749 (24% of world total)
- Sheep = 171 718 980 (16%)
- Goats = 305 659 769 (33.5%)

Southeast Asia – 38 188 990 (1.92% of world total)
- Sheep = 11 715 175 (1.1%)
- Goats = 26 473 815 (2.9%)

Central Asia – 57 123 723 (2.9% of world total)
- Sheep = 46 817 000 (4.3%)
- Goats = 10 306 723 (1.1%)

West Asia and the Middle East – 104 300 846 (5% of world total)
- Sheep = 75 769 940 (7%)
- Goats = 28 530 906 (3.1%)

Africa – 609 022 313 (31% of world total)
- Sheep = 299 031 760 (28%)
- Goats = 310 890 553 (34%)

Northern Africa – 171 368 910 (8.6% of world total)
- Sheep = 110 021 270 (10%)
- Goats = 23 254 000 (2.6%)

Eastern Africa – 150 324 039 (7.6% of world total)
- Sheep = 58 775 230 (5.5%)
- Goats = 91 548 809 (10%)

Southern Africa – 40 324 744 (2% of world total)
- Sheep = 28 716 710 (2.77%)
- Goats = 11 626 034 (1.3%)

Western Africa – 215 749 920 (10.9% of world total)
- Sheep = 92 635 850 (8.6%)
- Goats = 2 114 070 (1.3%)

Central Africa – 32 136 700 (1.6% of world total)
- Sheep = 8 882 700 (0.01%)
- Goats = 23 254 000 (2.6%)

(United Nations, 2010).

Predominant Breeds

Native breeds of small ruminants most predominant in the geographic regions where they are found are also known by local names and may be found in more than one region. Uses of the breeds are for meat, milk, and fiber, listed in parentheses after the breed names. The countries that are included in these regions are based on the United Nations Food and Agriculture Organization FAOSTAT website list, and details of specific breeds can be found in the list of relevant websites section at the end of the article.

East Asia – Cambodia, China, Mongolia, North Korea, South Korea, and Taiwan
- Sheep – Altay (meat); Karakul and Kazakh (meat and fiber); and Khalka (meat, wool, and milk)
- Goats – Dagris, Baladi, and Shami (meat)

Central Asia – Azerbaijan, Kazakhstan, Kyrgyzstan, the Republic of Georgia, Russian Federation, Turkmenistan, Tajikistan, and Uzbekistan
- Sheep – Akhar Merino, Sargin (wool); Adal (meat and wool)
- Goats – Orenburg, Altay (mohair); Adal (meat and fiber)

Southeast Asia – Bangladesh, Bhutan, East Timor, India, Indonesia, Laos, Nepal, Pakistan, Malaysia, Myanmar (Burma), the Philippine Islands, Sri Lanka, Thailand, and Vietnam
- Sheep – Arabi, Balkhi, Araghi, Baluchi dumda, and Karakul (meat and wool); Kandahar Gadik and local Javanese thin tailed; Priangan of West Java; and fat-tailed sheep of East Java (meat)
- Goats – Barbari, Boer, Jamnapuri, Kabuli, Kandahari, Tahiki, Watani, and Zaraby (meat and milk)

Western Asia and the Middle East – Bahrain, Iran, Iraq, Israel, Jordan, Lebanon, Oman, Pakistan, Qatar, Saudi Arabia, Syria, Turkey, the United Arab Emirates, and Yemen
- Sheep – fat-tail – Arabi; Awassi (milk); Baluchi; Ghezel; Karakul; Taleshi, (wool); thin tail – Damani (meat, milk, and wool); Waziri (meat and wool); Assaf (meat and milk); and Balki (meat)
- Goats – Baluchi, Baladi, and Damascus (Shami) (meat)

Northern Africa – Algeria, Egypt, Libya, Morocco, South Sudan, the Sudan, Tunisia, and Western Sahara
- Sheep – Algerian Arabi; Uda; the Sudan; Tunisian Barbary – hair sheep (meat); Rahmani (meat, milk, and wool)
- Goats – Nubian (meat and milk)

Southern Africa – Botswana, Lesotho, Namibia, South Africa, and Swaziland

- Sheep – fat tailed – Blackhead Persian; Danakil (Adal); Damara; Dorper; Meatmaster; Pedi; Van Rooy; Zulu (meat); Dohne Merino; South African Meat Merino (meat and wool); Namaqua Afrikaner; and Ronderib Afrikaner (Cape fat tail) (meat and pelts)
- Goats – Boer; White Savannah; Nguni; Pedi (meat); and Angora (mohair)

Eastern Africa – Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Madagascar, Malawi, Mauritius, Mozambique, Reunion, Rwanda, Seychelles, Somalia, Uganda, the United Republic of Tanzania, Zambia, and Zimbabwe

- Sheep – Adal; Berbera Blackhead; Danakil; Masai (Red Masai); Tanganyika Short tailed; East African Fat-tailed type – hair sheep (meat)
- Goats – East African (meat); Galla (Bora and Somali) (milk); Kenyan dual purpose goat (meat and milk); Nubian (meat, milk, and hides)

Western Africa – Benin, Burkina Faso, Cape Verde, cote d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, and Senegal

- Sheep – Uda; Cameroon Sheep – hair sheep (meat); Peul; Bali-Bali; Maure; Guinea Long legged; West African Long legged – hair sheep (meat and milk)
- Goats – Djallonké (African, West African Dwarf, and African Pygmy); Chevre Naine, Chevre de Casamance, Hausa, Kosi, Mossi, Cameroon Grassland, Kirdi, and Kirdimi (meat); Boer; Guinean goats (meat); Sahelian (Fulani and Tuareg) (milk, meat, and skins)

Characteristics and Species Differences

Environmental changes over the centuries have influenced human and animal movements as well as adaptation and coping strategies. Many morphological differences of small ruminants evolved with their domestication as breeding for specific traits became important. Hair or wool sheep, fat- or thin-tail sheep, and fat-rumped sheep are examples as are breeds of goats that produce dairy, meat, or specialized fiber, such as cashmere or mohair.

In tropical regions of Africa and Southeastern Asia, hair sheep are most common.

As all sheep have a mix of hair and wool fibers, the difference between hair and wool sheep is the ratio between the two kinds of fibers the animal contains. This ratio depends on the origin and the climate in which the stock is produced. In more arid and hotter regions, hair fibers outnumber the amount of wool fibers, resulting in a shorter and smoother hair coat with very little wool. In colder climates, the opposite ratio occurs, producing a greater number of wool fibers versus hair fibers. Difference in management relates to labor required for shearing (wool sheep) versus combing or natural shedding (hair sheep). There are also differences in traits and characteristics of hair versus wool sheep, for example, hair sheep have lower reproduction efficiency but higher tolerance for arid climatic conditions without major loss of productivity and survival ability when feeds are limited or of low nutritional value (Bradford and Fitzhugh, 1983).

In extremely arid regions, such as Mongolia, Northern India, Pakistan, Western China, Central Asia, the Near East, the Middle East, and Southern and Eastern Africa, some sheep breeds have survived since 2400 BC. The unusual characteristic is the high level of fat stored in the rump and tail, which is a reserve source of energy during periods of nutritional stress for the sheep as well as a food product for human use. For this reason, fat-tail sheep are rapidly replacing the native thin-tail breeds in Indonesia, especially on the island of Java.

As with sheep, goats in arid/semiarid climates or other extreme environments exhibit characteristics that enable them to survive and thrive where temperate climate breeds might not. In pastoral societies where livestock are produced on rangelands of variable forage quantity and quality, goats can survive in harsh or degraded environments by maintaining body condition during feed or water shortages. They are able to walk for very long distances in search of food and exhibit ability to find and assimilate browse that sheep or cattle cannot use. Females have low abortion and stillbirth rates, produce strong kids at birth that aids in survival rates, and produce good yields of milk. A combination of such traits provides a level of protection against other risks in the production system (Fitzhugh and Bradford, 1989).

Although most domestic goats are produced at lower altitudes, a few breeds produced for fiber, specifically pashmina or cashmere, are raised at high altitudes where extremely cold winters prevail. The high Himalayas and the Gobi desert in both Inner Mongolia and Mongolia are such regions. The Pashmina or Changra breed thrives in this environment. The inner wool (cashmere) grows in the winter and is shed in the spring when it is collected and spun. One characteristic of this breed that is different from sheep and other goat breeds is that it eats both grass and grass roots. As a result, mismanaged grazing of large herds can produce significant environmental damage.

Behavior

One common behavioral difference between goats and most sheep breeds is the instinct for sheep to bunch together for mutual protection. Sheep are more clannish than goats due to a strong gregarious tendency and innate need for protection where natural predators can be found. If cornered, sheep may try to escape or maintain an aggressive behavior posture. Goats are more inquisitive than sheep and explore their surroundings independently rather than as a herd. They display a more assertive behavior than sheep and are less likely to run from apparent danger.

Feeding habits

Most breeds of sheep are selective grazers due to their anatomical split-lip structure that enables them to thrive in environments that have variable forages. Taste buds develop in the fetal stage and the lamb begins to nibble available feeds soon after birth. Depending on the production system, the availability of forage or feed varieties may be limited, thus reducing the choices sheep have. However, some breeds, such as Dorper, Meatmaster, and Blackhead Persian, are nonselective and tend to browse like goats. This enables them to access a higher level of nutrition than other breeds and be productive in environments where other breeds might not survive.

Sheep thrive in monoculture pastures, whereas goats require forage variety. Hence, they browse to select a diet that includes tree or shrub leaves, twigs, grasses, weeds, and roughages, often climbing up trees to access the leaves or standing on hind legs to reach lower hanging branches. They tolerate bitter tasting plants better than sheep (which may account for browsing forages more bitter than grasses) as well as reject urine or feces-tainted forages. Like camels, goats can tolerate limited water intakes, whereas sheep require a more consistent supply. When temperatures reach the 100 °F mark (38 °C), goats pant less than sheep, thus reducing moisture loss through sweating as well as feces and urine elimination (Devendra, 1989).

Genetics

Tropical ruminant breeds vary in genetic potential for a variety of traits. Positive traits include heat tolerance, disease, and parasite resistance. Some examples include the Red Masai sheep, which is genetically resistant or less prone to infestation with intestinal worms; Uda sheep of Northern Nigeria, which are much less susceptible to foot rot; and the Dorper, the second most common breed in South Africa, has low susceptibility to internal and external parasites. The West African Dwarf goat, the predominant breed of the humid tropics from southern West Africa through Central Africa, is trypanotolerant. The Savanna goat is heat and pest tolerant, adapts to mixed climates, needs little management, and has a natural resistance to tick-borne diseases, such as heartwater and other external parasites. Similarly, the Djallonké breed is trypanotolerant and resistant to parasitic diseases.

As noted, fat-tail sheep breeds are tolerant of extreme aridity, whereas cashmere breeds of goats are adapted to an extremely cold environment.

Smallholder Production Systems

Classification of Systems

In developing countries, the term 'smallholder' is used to describe producers with limited resources, i.e., resource-poor or subsistence farmers. This definition may differ among countries and agroecological zones as economic strata exist within all production systems (Dixon *et al.*, 2004). In terms of agricultural systems, the three most basic resources are land, labor, and capital. Access to inputs and supplies are additional necessities.

Pastoralists could be classified as resource-poor producers as they provide labor for raising livestock but rarely own the land their livestock graze on. However, not all pastoralists are resource poor. Livestock are their capital and have been termed a living savings account. This section applies the resource-poor or smallholder producer definition to pastoralists as well as to nonpastoralists, given that the majority of them fit the definition.

Livestock production systems in developing countries are commonly described by the ecosystem conditions in which the animals are raised. Several production systems can be found within the same country depending on the environment, ecology, and human population size as well as on economic and sociocultural factors that promote or inhibit specific livestock species from being produced. Management practices, including gender roles, differ according to system as does the nutrition of livestock, reproduction rates, and health challenges. Climate change is impacting traditional systems, and the interactions among livestock and environmental and human health (including human nutrition) is dynamic. Production systems are changing as producers adapt to climatic changes or adopt coping methods to preserve their traditional practices as best as they can.

Regional environmental conditions are used to define livestock production systems.

The primary livestock production systems and the environments in which they are found are:

- pastoralism/agropastoralism (extensive, rangeland based/partially settled) – arid and semiarid zones;
- integrated mixed crop–livestock (crop-based) – humid/subhumid zones;
- intensive (large numbers of animals in confined conditions) – temperate zones; and
- periurban/urban (around or in cities or slums) – humid/subhumid zones and temperate zones.

The geographic regions where these environmental zonal systems are located are:

- arid/semiarid zone – North and West Africa, East Asia (Mongolia), South America (Andean Mountain range or Altiplano), Western USA, and Northern Australia;
- humid/subhumid zone – parts of Africa (coastal zones and southern region), South and Latin America (northern Andean mountain range), and South Asia; and
- temperate zone – Americas, Europe/Eastern Europe, and New Zealand.

The focus of this section is on smallholder production systems in the arid/semiarid zones of North and West Africa and of East Asia and the humid/subhumid zones of coastal zones and southern region of Africa and of South, Southeast, and Central Asia extending into parts of the Middle East.

Each of the production systems includes sheep and goats, although populations vary depending on culture, uses for their products (meat, milk, fiber or skins, manure, generation of household income, or barter), climate, input availability including service delivery (such as animal health), and availability of labor. Because many breeds are adapted to harsh environmental conditions and can convert lower quality forages into usable products, the species fill an important need in developing country smallholder production systems. They are used to diversify risk from failing crop harvests or lack of feed for large ruminants due to drought or floods or from economic shocks resulting from low prices for crops. Because they reproduce more quickly than cattle, they provide a quick return to investment (Gutierrez, 1985).

The two most commonly found systems in developing countries of the Asian and African regions are pastoralism/agropastoralism or mixed crop–livestock systems in the humid/subhumid zones. Pastoralism involves grazing larger size herds or flocks than mixed crop–livestock systems where animals most commonly are confined (Safilios, 1983).

Pastoralism/Agropastoralism

Extensive, rangeland based/partially settled – arid/semiarid climate

Description of system

Both the northern and southern hemispheres contain arid and semiarid desert climates. These are defined as areas with short growing seasons where rainfall ranges from 0–300 mm to 300–600 mm, respectively. Owing to intense dry heat and light winds moisture evaporates quickly. Average air temperature is 16 °C. Arid deserts cover 12% of the Earth's land surface (Lohmann *et al.*, 1993).

A semiarid climate predominates in regions between the arid deserts and more humid climates. Average temperatures are 24 °C (43 °F) and annual precipitation varies from less than 10 cm (4 in.) (Lohmann *et al.*, 1993) in the driest regions to 50 cm (20 in.) in the moister grassland steppes of Eurasia in the Ukraine and east into Russia. Semiarid conditions also exist in colder highland climates, such as the Andean Mountain range in South America, Mount Kilimanjaro in Africa, and the Tibetan Himalayas.

Seasonal migration is an important characteristic of pastoralism because it enables access to forage as well as breaks up crusted soils as herds/flocks transit the land. Small ruminants are combined with large ruminants (cattle or camels depending on location) to diversify risk. However, sheep may compete with cattle or wild sheep or other herbivores for limited grazing resources.

Air temperature and rainfall determine the ecology of arid and semiarid ecosystems and thus influence the use of the land. Intense heat, low levels of readily available water often at great distance between sources, and lack of forage or grasses affect the smallholder's choices of species and breeds of small ruminants that can be raised in the region. A producer's lack of access to higher quality feed, animal health supplies, technical advice, and availability of markets for the livestock influence decision making, adoption of new practices, or adaptation to situations unfavorable to increasing numbers of animals or improved genetics.

Pastoralism is an important production system in the drylands – nearly half of the land area of sub-Saharan Africa and one-third of the world's land surface. It contributes significantly to food security in the Horn of Africa and a source of livelihood for approximately 200 million people worldwide (Nori *et al.*, 2005).

Although there is no annual census of global pastoral/agropastoral populations, it has been estimated that approximately 120 million produce livestock worldwide, of which approximately 42% reside in sub-Saharan Africa. The Sudan, Somalia, and Ethiopia contain the largest populations. However, in some countries pastoralists represent the majority of the population (Rass, 2006). The number of animals raised by these populations varies with climate, the availability of water, and forage. As of 2010, Western Africa had a larger number and proportion of small ruminants than Eastern Africa (United Nations, 2010).

Geographic location, social organization, national government policies, national economic status, and evolutionary history of people and animals combine as parameters that influence production practices. Pastoralists migrate in set patterns taking with them their flocks as well as family members, moveable shelters, and food. Agropastoralists are partially settled and produce a small amount of crops to feed the family members that remain at the household while other members migrate.

Livestock management practices

Pastoralist managerial practices include movement and migration with livestock; supplementing livestock with feeds when necessary and if feeds are available; coping or adapting to extreme weather variations; determining whether to sell animals during crises; and disease management if technical assistance or supplies are available, accessible, and affordable. Sociocultural practices of pastoral communities serve to bond related families and provide a foundation for protection or compromise when others compete for rangeland forage and water.

Gender roles are well defined irrespective of whether they are pastoralists or agropastoralists. An agropastoralist family divides during specific seasons, leaving the women and young children at the residence, whereas men and older boys migrate with flocks in search of forage and water. Women and young children often raise a few sheep and goats within the household area. Social norms in pastoral societies confer small ruminant management as well as milking, milk processing and sales, and use of milk for domestic consumption on women. Women may also be traders or marketers of small ruminants, although this depends on their level of business knowledge and the latitude of societal norms in their subculture. These might include whether or not they are allowed to own or have access to livestock assets, their status as single or married women, whether or not they head the household due to absence of a spouse, and the predominant roles of the men in their subculture (Sikana *et al.*, 1993; Ridgewell and Flintan, 2007; Aklilu and Catley, 2009).

Livestock nutrition

Zonal ecology determines primary feeds or forage that varies by location. Both sheep and goats shift preference from forage classes and grasses in the wet season to browse in the dry season. Trees, shrubs, subshrubs and grass, moist, broad leaf, wooded savannah, and dry thornbush scrub are among forage browsed by goats in this agroclimate. As grazers, sheep are more limited in forage selection depending on the geographic areas and ecosystem in which they are raised. Seasonality and the availability of grasses or browse may influence a pastoralist's mix of species in the herd (Sidahmed, 1996).

Livestock reproduction

Pastoralists are extremely familiar with the animals in their herds/flocks and employ identification systems similar to large-scale producers in nonpastoral systems. Selection factors include animal body size, level of milk production, drought tolerance, and parent and grandparent features. One study in Northern Kenya documented the intricate memory system some producer groups used (Mbuku *et al.*, 2010). Record keeping also includes dates of birth, castration, new stock, weaning, culling, performance, and health (Ayantunde *et al.*, 2007). Ear notching and coat color are two physical means of identification.

Certain groups select animals for breeding based on body size and milk yield, whereas drought tolerance, fertility, mothering ability, and prolificacy are less important. Other producer groups consider large body size, drought tolerance, and offspring quality as important but fertility, meat or milk production, and mothering ability as less significant. Therefore, although producers may use similar criteria for selecting breeding stock, they differ in which traits are most important for individual consideration. A high level of productivity, although important, is not always the most significant factor. Some breeds or types are recognized for specific products and are selected primarily to produce meat (e.g., South African Boer, Galla, and East African goats), milk (e.g., Somali and Jamunapari), or fiber (cashmere). One important drawback to selecting for high productivity traits is that such animals may exhibit lower resistance to disease or adaptability to long droughts and decreased availability of water or forage.

Livestock health challenges

In this production system, primary health challenges are: Peste de petite ruminant (PPR), brucellosis (primarily in goats), circling disease, helminths, Q fever, contagious caprine pleuropneumonia (CCPP – a major disease of goats), capripox, ticks and tick-borne diseases, tsetse flies and trypanosomiasis, anaplasmosis, babesiosis, and cowdriosis. Vaccines and medications are in use for many of the diseases, but pastoralists may not be able to access or afford them. Weather events, such as prolonged and more frequent droughts, aberrant rainfall, or flooding, are occurring more frequently and unexpectedly, resulting in higher numbers of livestock displacements, sickness, and death. These events are creating microenvironments that are optimal for disease pathogens or vectors to occur where they have not been found before, forcing livestock and producers to confront greater health challenges than in the past.

Integrated Mixed Crop–Livestock and Periurban Production Systems

Crop-based – Humid/subhumid climate

Description of systems

Humid and subhumid climatic zones include tropical forests and savannas, where seasonal changes result in very wet and very dry seasons, and boreal and deciduous forests. Temperatures range from 16–18 °C (60–64 °F) in the savannas and rainforests to 31 °C (56 °F) in deciduous forests. Although boreal forests are considered to be humid, one exception is Western Siberia where precipitation is low, thus creating a subhumid or semiarid climate type. There is a wide swing in temperature through the year with lows of −25 °C (−14 °F) and highs of 16 °C (60 °F). Referencing the Koppen–Geiger climate classification system, annual precipitation varies widely depending on geographic location and ecosystem from a high of 262 cm (103 in.) in rainforests to 0.25 cm (0.1 in.) in savannas.

The Amazon Basin, Congo Basin of equatorial Africa, and the East Indies from Sumatra to New Guinea are all classified as humid/subhumid tropical rainforests. Savannas are found in India, Indochina, West Africa, Southern Africa, South America, and the north coast of Australia. Northern China and Central and Eastern Europe contain deciduous forests. Boreal forest climates are in Central and Western Alaska, Canada, from the Yukon Territory to Labrador, and in Eurasia, from Northern Europe across all of Siberia to the Pacific Ocean. Small ruminants can be found in all of these regions.

Increasing urbanization has led to income inequities, economic insecurity, and urban poverty, forcing some smallholder producers to earn income from off-farm labor, although opportunities may be limited. To supplement such income smallholder producers may raise small ruminants as a secondary activity for household food security. Because of their small sizes and lower cost of production than cattle, sheep and goats fit the limited resource base of urban and periurban households (Waters-Bayer, 1995). Smallholders prefer to raise goats because they require less management and are hardier than sheep. Because they are browsers, goats forage widely and are able to meet their nutritive needs, albeit at suboptimum levels at times (Wilson, 1991). A common reason that households often need cash is to pay school fees, healthcare, or unanticipated emergencies. In some societies, small ruminants are kept for religious or social reasons. For example, Muslims prefer sheep for religious festivals when rams are slaughtered to provide meat for the household. Other social occasions include naming ceremonies and birthday celebrations.

Like other production systems, urban/periurban livestock producers face economic sociocultural and institutional constraints. Availability, access to, and affordability of inputs, supplies, and technical services may constrain smallholder producers scaling up their enterprises. Other important factors are land tenure, access to markets, lack of credit or working capital, and other forms of assistance when needed.

Credit is very often a major limiting factor for building or improving infrastructure for animals, for purchasing additional numbers of animals, or for buying routinely used animal health products. Unless rural banks are established and are accessible by community members, producers often lack collateral required by financial institutions. In addition, producers may encounter difficulties in repaying loans due to low rates of return on their investments.

Livestock management practices

The importance of small ruminants in this production system is similar to the pastoral/agropastoral system. However, management practices differ in that the flocks/herds are much smaller due to the land base on which they are raised; the greater availability of water and forage, including crop by-products; and their affordability compared with a large ruminant. However, there is still competition with other farm undertakings for land, capital, and labor (Gutierrez, 1985). If tethered or confined there is a need to bring fresh grasses or legumes to the animals, thus requiring an individual who has time, energy, and strength to do so. This work often falls on women and children. The alternative is to use a controlled grazing system that also requires a shepherd who often is a child (Coop, 1986).

Because dairy goats are easy to handle, women and children assume their management. Management duties that women perform include milking animals, sale of dairy

products, castrating, delivery and attending to the newborn, and animal sanitation, including housing if used. In some societies, women sell the animals and use the returns for household needs, although the purchase of new stock remains the responsibility of the male in the household.

Owing to raising a small number of animals often in confinement, the cut-and-carry system for forage is a relatively common practice in periurban/urban systems but requires extra nonfamily labor that may fluctuate seasonally if family members cannot meet the need. Animal and human population density in the locality, cost of animal housing, availability of marginal lands for grazing or foraging, and whether natural pasture is available factor into the level of confinement under which small ruminants are raised. Similar to the mixed crop–livestock system, management decisions are made by the head of the household, usually the man, or if the animals are owned by an absentee landlord, by the owners themselves. Women or children are responsible for sanitation of animals, feeding troughs, and animal housing, but hired labor or family members of lower social status may also be employed.

Livestock nutrition

Mixed crop–livestock and periurban/urban production are traditional systems in the humid/subhumid tropics. Different patterns of crop production as well as the type of crops, including trees such as palm oil, coconuts, or rubber, enable producers to use crop residues and stubbles while providing organic fertilizer (dung and urine) to the land. In Southeast Asia, grazing animals under tree crops in association with tropical legumes adds value by increasing soil fertility, controlling waste herbage thereby decreasing the need for herbicides, and adding a second profitable element to the system (Devendra, 1986).

Many households keep only a few animals; thus, feeding is more labor intensive. Animals may be tethered in areas of intensive crop cultivation or confined to the household and fed various crop residues when available, in addition to grasses or shrub/tree leaves that are cut and carried to them (Devendra, 1986). Where families have access to grazing, for example, along roadsides or marginal field areas, more extensive grazing is practiced. Families may combine their flocks/herds during the day under management of an unpaid family member or shepherd who returns them to the households in the evening.

Cereal cultivation of maize, rice, and wheat provides stubble, and other residues may include sweet potato vines or sugarcane tops, although the level of nutrition is general. Supplementing the diet with tree leaves, pods, and seeds, especially leguminous ones like leucaena, cassava, jackfruit, acacia species, sesbania, and gliricidia, adds additional nutrients (Devendra, 1983; Hutagalong, 1981).

Livestock reproduction

Because producers in mixed crop–livestock systems rely on both crops and livestock for household income generation, raising small ruminants that are highly productive is important to management decisions. The type of species, cost of animals, products derived from the species, access to markets, consumer demand for the products, availability of labor, availability and access to technical services, and inputs all contribute to a producer's ability to maintain a viable farming enterprise. Sheep and goats fill an economic niche but must be productively profitable. This requires breeding stock that can add value to a household herd or flock as well as a level of technical understanding about livestock nutrition and health.

In the periurban/urban system, the primary source of household income is off-farm work. Small ruminants act as a repository for rural capital ('living savings bank') and provide a high return on investment (often more than 10%). In poor households, livestock – especially small ruminants – are a key means of managing risk, protecting savings, and offer insurance against drought and crop failure due to changes of climate patterns. Successfully breeding the household's limited stock serves to reduce the expense of purchasing replacement animals.

Livestock health challenges

The humid/subhumid climate in which these production systems occur is ideal for parasite and disease vector multiplication and spread. High ambient temperature and humidity create an environment conducive to internal and external parasites, bacteria, fungi, mosquitoes, and flies that act as disease vectors. Genetic characteristics often limit disease resistance and weak management practices can provoke disease transmission.

Small ruminants are subject to a daunting list of diseases and parasites. Viral and bacterial diseases include: PPR, CCPP, Rift Valley fever, sheep pox, salmonellosis, brucellosis, anthrax, hemorrhagic septicemia, heartwater, schistosomasis, Nairobi sheep disease, enzootic abortion of ewes, foot-and-mouth disease, bluetongue, Crimean–Congo hemorrhagic fever, pneumonic pasteurellosis, contagious pustular dermatitis, coccidiosis, tetanus, black quarter (*Clostridium chauvoei*), botulism, enterotoxemia, contagious ecthyma, caseous lymphadenitis, hypocalcemia, mastitis, transit tetany, foot rot, and trypanosomiasis. Some indigenous breeds are tolerant of trypanosomiasis, such as the West African dwarf sheep and goats and East African goats (OIE Documents Database).

Internal parasites include helminths that cause Haemonchus contortus, liver fluke, roundworms, lung worms, tapeworms, nasal bot, and bloat. Common external parasites are ticks, fleas, lice, and mites.

In periurban/urban production systems, zoonotic diseases become more significant when livestock are raised close to household premises, or within the household dwelling itself. Lack of food safety standards also exacerbate human health threats. Traditional producers are aware of the role of management in disease avoidance and control but may lack the ability to prevent their occurrence (Ntifo-Siaw and Ghartey, 1988). Zoonotic diseases are particularly important, especially brucellosis, tuberculosis, animal-sourced foodborne gastroenteritis, *Tenia solium* neurocysticercosis, and *Mycobacterium bovis* tuberculosis. The *Fasciola*, *Entamoeba*, and *Giardia* species and *Balantidium coli* are especially significant in these systems (Kagira and Kanyari, 2001). Both humans and livestock are vulnerable to the diseases these parasites transmit (Harper and Penzhorn, 1999; Kanyari *et al.*, 2009).

Values of Small Ruminants

Livestock represent diversified values – sociocultural, environmental, economic, and nutritional – and not all of these

can be measured in hard numbers. Nor can one value be equated with another, particularly across cultures and ecosystems. Livestock serve as critical components for poverty alleviation, for conflict mitigation, prevention, and resolution. In some societies animals represent social value, for example, status in the community often based on the number of animals a household owns. Instead of a dowry payment by the bride's family, a practice once widespread in the West, some cultures use cattle, sheep, and goats as bride price. Payment is made by the groom's family to secure the woman's hand in marriage.

But they also serve as a valuable entry point for promoting gender equity in rural areas. Women play an important role in livestock management through animal genetic selection, milking, processing, and marketing as care providers, feed gatherers, and birth attendants. Identifying and supporting women's roles as livestock owners, processors, and users of livestock products and strengthening their decision-making power and capabilities are key aspects of promoting women's economic and social empowerment.

Smallholder producers benefit at various economic levels by keeping small ruminants. Small ruminants produce meat, milk, fiber, and hides. The levels of production and economic importance of these products vary among regions, especially in the developing countries. Sheep and goats are often cited as a hedge against natural disasters, economic shocks, and rising food prices, particularly in situations of small or failed crop harvests. They fill nutritional and economic gaps and are a coping mechanism until the next cropping season. Dairy sheep and goats can produce enough milk for household use as well as supply local markets, and the nutritional values are almost equivalent to cow milk, although compositions vary by breed, animal, and point in the lactation period. However, sheep milk is higher in fat, energy, sugars (lactose), and calcium and slightly lower in water (U.S. Department of Agriculture, 2012). Small ruminants produce meat, milk, fiber, and hides. The levels of production and economic importance of these products vary among regions, especially in the developing countries.

Production trends in the developing countries parallel consumption trends. The FAO estimated that in 2010 developing countries would produce 143 million tons of meat. Of this volume, 45% would be pork, 25% poultry, 23% beef, and 7% mutton or lamb and goat meat. Yet, as a group, developing countries were expected to increase net meat imports twentyfold, amounting to 11.5 million tons in 2020. Of net meat imports, beef was expected to constitute 46%, poultry 30%, pig meat 13%, and sheep and goat meat 11%.

Total sheep and goat milk production globally amounted to 27 465 619 ton in 2010 (United Nations, 2010). Of this total, 49% was produced in the Asian region and 44% in the African region. Global sheep and goat meat production during the same period totaled 60 285 054 ton, of which Asian region countries produced 7.5% and African region countries produced 4.7%. The top five countries producing these products were located in Asia and Africa and the majority, if not all, of the milk and meat was produced by smallholders.

Positive environmental values, especially those of raising livestock on the range and grasslands, include mineral and nutrient cycling; enabling soil conditions for storing soil carbon, water cycling and/storage (grass/vegetative cover can capture 50–80% more water than bare ground), and improving the diversity of grasses by dispersing seeds and breaking up the soil crust. In pastoral societies, livestock consume forage on lands that cannot produce crops, thus changing these areas into food-producing landscapes. Sixty-five percent of global dryland area is grassland used for livestock production by 800 M people (Mortimore *et al.*, 2009).

Pastoralists graze livestock on lands that cannot produce crops, thus turning them into food-producing landscapes. Grasslands represent major terrestrial carbon stock, are approximately half the emerged ice-free world, and represent approximately 70% of world's agricultural area. Good land management results in reduced risk of drought and floods, greater permeability, and increased water-holding capacity in soils, both of which are examples of direct benefits up- and downstream. In fragile environments as are found in arid/semiarid ecoregions, goats add value to the grazing system due to their ability to browse forage species, including weeds, that other species do not.

Nutritional value

Animal source foods (ASF) reinforce household food security. One of the most difficult and least accounted values of livestock is the nutritional merit of ASF. From the early 1970s to the 1990s, meat and milk consumption in developing countries grew by more than twice the increase seen in developed countries and more than half as large as the increase in cereal consumption resulting from the Green Revolution. Developing countries now consume close to half of the global meat supply.

On a global basis, foods of animal (including fish) origin provide approximately 17% of the energy and more than 35% of the dietary protein for humans. In rural areas of developing countries, diets of children are primarily crop based and often deficient in vitamin A, vitamin B_{12}, riboflavin, calcium, iron, and zinc. ASF contain more bioavailable levels of essential minerals and vitamins and provide concentrated sources of energy and fat, vitamin B_{12}, riboflavin, vitamin A, vitamin E, iron, zinc, calcium, and vitamin D. Vitamin A in its usable form and vitamin B_{12} is present only in animal source foods. Animal proteins are 20–30% more digestible than plant proteins (96–98% vs. 65–70%) and contain higher, more bioavailable levels of essential minerals and vitamins. Vitamin A in its usable form and vitamin B_{12} are present only in ASF. Vitamin A is an important micronutrient for the cognitive and physical development of children (Murphy and Allen, 2003).

Glossary

Coevolution People, animals, plants, and the land changed over time together in complementary ways.
Fictive kin Individuals included in a family unit through ceremonies, such as baptism and weddings, which involved mutual obligation of those serving in the ceremonies.
Hegemony The ability of one group to enforce its way of valuing people, actions, and things on another.
Land titling Granting title to a land previously held in common, by the state or a large landlord.
Pastoralists People who herd animals from place to place, depending on the season and availability of pasture.
Verticality Farming at different altitudes.

Introduction

Culture determines the way humans see the world, including how they link the seen and the unseen. It emerges as humans interact with each other and their environments. As a result, culture both shapes and justifies behavior, human interactions, and collective identity, including those related to food, water, and fiber production, processing, procurement, and consumption. Traditional agriculture is a way of preserving culture – an important anchor in an ever more chaotic world of globalization and climate change.

When traditional agriculture is destroyed, so is the culture and the people's relation to the land and to each other. Social justice is denied when traditional agriculture and the societies it supports and support it are destroyed in the name of progress.

Cultural Capital and Traditional Agriculture

Traditional agriculture coevolved with people who practiced it in different ecosystems, contributing to human health in terms of food and diet. Food and the ceremonies surrounding food are an important part of traditional agriculture and the well-being of the groups that practice it.

Cultural capital links the seen and the unseen. In Northern countries, it is referred to as 'world view' or *Weltanschauung*. In Spanish America, it is best referred to as cosmovision. It includes symbols, a sense of place (or lack thereof), ways of knowing, language and history, ways of acting, and what is believed to be possible to change.

A keen awareness of the land and its characteristics (WinklerPrins and Barrera-Bassols, 2004) was part of the cultural capital of precolonial societies in Mesoamerica and the Andes (Williams, 1975; Barrera-Bassols *et al.*, 2006), as well as other parts of the world. Rituals and ceremonies honored the Earth and human mindfulness of it (Bolin, 1998). But settled societies and colonization separated cultural capital and agriculture, separating people from the land and from each other.

The cultures of traditional agriculturalists define how they relate to each other, to the ecosystem, as well as what and how they produce and consume. Hegemony is the ability of one group to impose its culture – the beliefs about what should be and what is possible to change – on others. Thus for dominant cultures, their values reinforce the primacy of increasing production to generate money, and other values are viewed as sentimentality and blocking progress. These hegemonic values are then translated into laws that often deprive indigenous people of their land (Alden Wiley, 2012).

For smallholders, in particular, cultural capital includes the way soil and water are classified, the uses for which it is deemed most suitable, and the things that must be done to maintain its fertility and purity, including terraces, crop rotations, soil amendments, ceremonies, and prayers. The cultural aspects of maintaining soil and water were inseparable from traditional agriculture and herding.

Some smallholders, often members of specific ethnic groups, have been in a place hundreds of years to develop a culture of land and water and how to use them. They classify and protect soils and water sources based on observation and generations of experience (Williams, 1975). Other smallholders are driven to marginal lands as mining (including petroleum exploration) and industrial agriculture forces them off their ancestral lands. Particularly, as smallholders moved onto marginal lands, few believe they can do much to improve the soil on their new, often degraded, land. They may seek to grow crops they traditionally grew, whether adapted to the new ecosystem or not. The practices that worked in the context they came from are often not transferable to the new setting. They do not understand local hydrology or seasonal variations in precipitation that are unlike where they came from.

The 'chacra' in Latin America is the place where one grows or cultivates plants of human interest (Rengifo, 2004). A 'chacra' is not only defined and delimited by humans, but also by the nature and gods. The traditional 'chacra' serves multiple purposes in human livelihoods, serving to reproduce not only the human body by producing food, but also collective identity in reproducing spirituality.

Rengifo (2004) identified three important cultural aspects of the Andean farm field (chacra):

1. the relation between cultivators and their crops is personal,

 doi:10.1016/B978-0-444-52512-3.00099-1

2. agricultural practices are performed as rituals, and
3. a fine and detailed conversation with nature is necessary to undertake agricultural work at a proper time, in a proper place, and in a proper way.

Revilla (2006) shows that the effect is most important than rationality, communal sentiment predominates over individualism, and humans continue to be part of nature, rather than seeking to control it.

In 1990, there were more than 460 different ethnic groups in Latin America that still managed local ecosystems with indigenous technologies (Altieri and Hecht, 1990). The ethnoecological knowledge of some of these groups is impressive. For example, the Mayans recognize approximately 908 botanical taxa and the Huastecos of Mexico, approximately 861 (Toledo, 1992). This indigenous knowledge has led to management systems now considered sustainable and, therefore, proper to guide modern resource management. Sustainable traditional farming systems still in existence include the *chinampas* (small rectangular areas of fertile arable land to grow crops on shallow lake beds) of Mexico, the *waru waru* raised bed cultivation in the Andean *altiplano*, and the agroforestry systems of several Amazonian tribes. These small landholders use a very diverse array of traditional slope, water, soil, pest, and vegetation management techniques, which include composting, rotations, polycultures, agroforestry, and watershed management systems (Altieri, 1987; Wilken, 1987; Altieri and Masera, 1993).

Similar intersections of culture and microecosystems occur around the world. For example, in oasis agriculture in North Africa, pastoralism in combination with intensive fruit and vegetable production is carried out only on the most fertile land (Ilahiane, 2004). Such cultural and farming systems have coevolved according to environmental conditions that are often ethnically specific and determined by intracommunal notions of change and community (Ilahiane, 1999).

Most traditional agricultural systems seek to minimize risk, both long term and short term (Rist and San Martin, 1993). In many steep regions, households traditionally farmed at various altitudes to capture the specific soil and climate conditions necessary for optimal production over time. However, the move to land privatization (usually done through titling contiguous land parcels) and large machinery has made such soil protection strategies socially difficult, and also mechanically impossible, as the traditional plots were small and intensively farmed. Diversification and verticality have both been diminished by modernization projects. Such practices were stigmatized or considered obsolete, causing the loss of some of the knowledge necessary to preserve soil quality.

Gender division of labor is an important part of smallholder agriculture, although those traditions are challenged as more and more men migrate to seek wage labor. Traditionally, men and women perform separate tasks within the same enterprise, suggesting that each gender can appreciate and enhance different aspects of soil quality. Often, men in Latin American smallholder households are in charge of plowing, women in charge of seed selection, both do planting and harvesting, men do tilling, and women do postharvest processing. In smallholders of Africa, there are women's crops (usually for household consumption or local sale) and men's crops (generally for an expanded market).

Cultural capital either values or denigrates social organization. It is social organization that has made smallholders in the Andes capable of overcoming the limitations of the verticality based in the community (Mayer, 1989), as traditional organizations have aided responses to drought and flood in other parts of the world. Shared cultural capital collectively maintains traditional agriculture. Managing the verticality means the community is concerned and acts in ways that maintain the soil and reduce risk from weather.

A major component of social capital, which is reinforced by cultural capital, is reciprocity. In many Andean communities, reciprocity is not an individual reciprocity only. Reciprocity has various forms (*humarapa*, *ayrí*, *mink'a*, and *waqui*) related to space and time and energy and mass. There are various types of reciprocity: work for a product, work for work, and work for food and party. Although in some reciprocity, it is individual to individual, in others it means that the group will act to support the group based on mutual commitment or that the individual will give to the group when there is a need in the understanding that they will receive help when they need it.

The *umaraqa* form of reciprocity in peasant communities has three categories of reciprocity: harvesting agricultural products, conserving soil, and in rituals, festivals, and fictive kin relationships (*compradazgo*). *Ayni* is another form of reciprocity that shares daily household work and tools. This tends to be more individual to individual reciprocity, generally among blood or fictive kin. *Mink'a* involves providing a service in return for a similar service, food, or the product produced by the work. *Waki* is where one person offers the field, the other the seed, and both work on the land from land preparation to seeding, weeding, and harvest. All of these forms of reciprocity depend on cultural capital and traditional patterns of farming.

Timing of planting of complex rotations was very important in the precolonial era. Fiestas and rituals marked the beginning and end of each phase of the agricultural cycle, which also helped to provide the family and labor needed. In some smallholder areas, these continued, although climate change has reduced their coincidence with appropriate soil moisture and soil temperature. As Bolin (1998) indicates, the rituals surrounding soil conservation and other farming activities, which still continue in some smallholder communities, enhance respect for the land, for its products, and for the members of the community.

The normative principle of precolonial agriculture was not the maximization of production but the management, conservation, and improvement of the fertility of soils over the long term, with social relations formed to meet the collective needs of the society within the limits of each vernacular ecosystem (Rist and San Martin, 1993). Social and cultural capital were critical for traditional agriculture and the rituals and ceremonies that supported it.

Relationship skills are important for building social capital. For many smallholders, building relationships with their neighbors is a part of their cultural capital. It involves mutual trust, in that smallholders know they can count on their neighbors when mutual action is needed. Reciprocity is a critical part of this – in some smallholder communities, participating in the *minga* (collective work for the community, including building roads and terraces to prevent soil erosion)

is critical for each smallholder contributing to the collective good. Mutual trust is established when different institutions and individuals can both give and receive. When mutual trust, reciprocity, and working in groups exist, a collective identity emerges and that collective identity can be embedded in the land.

Communal cooperation is necessary to conserve and rebuild the degraded soils. Building on existing social capital is critical, as such efforts require considerable collective investments of all the community capitals. Bridging social capital is necessary not only to bring in external knowledge, equipment, and funds, but also to help local people recreate what their ancestors did to protect the soil to provide continuous livelihoods.

Early Colonization and Separation of Agriculture and Culture

The Spanish colonists to the Americas brought with them the extensive agriculture of Spain, in contrast to the intensive agriculture of the indigenous populations. The kings of Spain rewarded the *conquistadores* with land concessions, called land grants, which included the labor of the indigenous people on the land, further stigmatizing the indigenous ways of farming and eating.

Although under the indigenous empires of the Inca, Maya, and others, agriculture was organized in ways that maintained the soil in place and covered and paid close attention to climate and precipitation. Under colonization, European forms of farming – which had depleted soils there – were introduced and indigenous farmers were left on the least productive and most marginal soils with less access to water.

Yet, through communal management of those lands, communities maintained soil fertility through rotations, fallowing the land (which facilitated the growth of cover crops), and judicious herding of animals with small soft hooves to maintain multilevel production systems for hundreds of year. The Spanish introduced new cultivars, particularly cereal grains, and livestock with small, hard hooves (sheep and goats) and large hard hooves (horses and cattle). They also introduced new agricultural technology, including plowing with animal traction, deforestation, and burning. All these technologies had negative impacts on soil carbon levels. To utilize animal traction efficiently, they abandoned the system of cultivation characterized by many small distributed fields at different altitudes that reduced risk by utilizing a variety of microclimates. They favored leveling the land and creating much larger fields in flatter areas, seeking greater efficiency in working the land. The hard-hooved animals, with their habits of eating entire plants, replaced the soft-hooved animals that had coevolved with the fragile ecosystems of the Andean plains, further degrading the soil and leaving it without cover. In the Andes, overgrazing affected the ecology of the main source of fuel, *taquia*, a low growing bush, causing a shift to wood for fuel, further destroying some of the natural protection for soils.

Rist and San Martin (1993) reported that the substitution of bread for potatoes as the mainstay of the peasant diet was extremely inefficient in terms of the comparative calories produced per unit of land – a factor of approximately four to one. Planting enough wheat to feed the population required clearing land that then quickly eroded. By the twenty-first century, much of the land was seriously degraded. Land degradation and the loss of traditional agriculture contributed to the decline in cultural capital as well as human capital, as families sent members out to earn income in other places. Under these colonially based systems, people kept their land, but not their traditional agriculture.

Separating People from Their Land, Their Agriculture, and Their Culture

Development Projects

Generally, the dominant group defines such imposition of new agricultural practices as 'progress' or 'development.' Many studies document the negative results of cultural deprivation in Australia (Hill, 1995), Africa (Kusiluka *et al.*, 2011), Asia (Colchester *et al.*, 2006), and the Americas. The impacts include decline in human health and well-being (human capital), income and wealth (financial capital), human interactions and social group support (social capital), and the ability of groups to express their norms and values to form policies (political capital) (Flora and Flora, 2013). When hegemonic norms and values deny the value of traditional cultures, but block access to fulfilling those of the dominant class, a sense of isolation and anomie can result in actions that degrade natural and built capital. For example, with initial colonization, dietary staples (principally wheat and meat) were transferred to settled states from the Americas, Australia, New Zealand, Asia, and Africa to provide low-cost wage foods in the rapidly industrializing colonial states (Friedmann and McMichael, 1989). The impact on traditional agricultures, the food they produced, and the health of the previous producers were simply unimportant under the new set of extractive values.

In the 1970s and the early 1980s, substantial international development resources were invested to 'improve' African pastoral system period. Some of the investments made no impact, while others were actually harmful to the environment and the pastoralists. (Park, 1992). Ellis and Swift (1988), based on long-term research in northern Kenya, argued that assumptions of development agencies that African pastoral systems with potentially stable (equilibrial) biotic feedback mechanisms (assumptions not based on research) have resulted in severely misdirected development programs. "[C]hanges in land tenure systems and existing institutions are assumed to be desirable and are therefore undertaken without consideration of what may be useful or valuable in the existing systems" (Ellis and Swift, 1988). Changes in these tenure systems, which influence land access for traditional agriculture systems, destroy cultural capital. Ellis and Swift showed that pastoralist systems in a variety of settings are persistent rather than equilibrial. The question then is how to aid persistence in an environment controlled by abiotic, chaotic forces, and not how to manage the equilibrium of the system with group ranches or grazing blocks. In this view, far from being irrational mismanagers, traditional pastoralists tend to be decidedly rational in reinventing survival systems in response to human-induced and natural ecosystem changes.

The cultural capital that governs norms and behavior in such systems is critical for the survival of the community as well as the ecosystem.

Spatial diffusion in northern Europe, Latin America, Africa, and Asia allowed pastoralists to persist relatively free of famine. However, demands for the land along their routes for grazing, logging, roads, tourism, sedentary agriculture, and mining have decreased use of this risk reduction strategy that is part of their culture (as are fights over land access). Because, no matter how remote, pastoralists are increasingly influenced by external human forces, and simply leaving them alone is not an option. "A cautious approach to pastoral development is to ask if intervention strategies can be formulated which will build on the best aspects of traditional systems, rather than imposing wholesale alterations on them" (Ellis and Swift, 1988).

Deliberate Attempts to Destroy Culture

There have been specific times in human history when overt attempts to destroy culture, by separating people from their land, had serious impacts on people, place, and biodiversity. Generally, removal from the land (often defined as 'civilizing savages') opened up the land for settlers and investors.

Earlier, US policy toward its indigenous inhabitants was conquest and removal. Indeed, at one point only one vote in the US Congress kept the policy from becoming one of total annihilation. The dominant culture, as represented by the Federal government in the 1820s, viewed indigenous cultures, varied as those cultures were among more than 600 separate tribal nations, as something to extinguish for the well-being of the United States. One way of extinguishing them was by removing the people from their land and changing that land by giving it to new settlers.

The US government practiced cultural annihilation by separation of cultures from the lands that nurtured them. Mechanisms for separation included military incursions and Indian wars (up to the presidency of Ulysses S. Grant), movement of nations to reservations, often far from the lands that gave rise to their culture (from 1870 to 1930s), and assimilation (attempted through boarding schools and through movement to urban areas). In addition, many European settlers used economic mechanisms and force to remove Indians from potentially valuable lands.

American Indian Boarding schools in the US were designed to 'get the red out' (Adams, 1995; Davis, 2001). The 'red' was the culture that resisted domination and land alienation. Culture included specific ways of hunting, gathering, and farming that allowed for survival of people in terms of the linkages between body and soul (Flora and Emery, 2011). This was attempted by removing Native American children from all symbols of their culture – their names, hair, food, clothing, religion, language, place, and extended families.

Stated in positive form (but equally devastating to the young people and their families), boarding schools were meant to 'civilize' Native American children. Boarding schools sought to replace indigenous ways of seeing, knowing, and being with English, Christianity, athletic activities, and a ritual calendar intended to further patriotic citizenship. All this was done under militaristic regimentation and discipline (Adams, 1995). Because they would no longer have the survival skills taught by their parents, the girls were taught how to cook and clean in European homes and the boys were taught to be mechanics and farmers, all skills irrelevant for most reservations where the indigenous adults were forced to live. They instructed students in the industrial and domestic skills considered appropriate to European American gender roles and taught them manual skills appropriate for an industrializing economy. For many Indian children, this cultural assault led to confusion and alienation, homesickness, and resentment (Adams, 1995; Davis, 2001). Traditional agriculture, which in its practices, linked people to each other and the land was denigrated (Grinder, 2004). Both traditional food and traditional agriculture, and the cultural links between them and the people, were denied.

Although separation from traditional agriculture was a deliberate attempt to change culture, there was another motive. The 'vacant' land became open for agriculture linked to industrial development.

Current Separations of People from Land, Traditional Agriculture, and Culture

More recent removal of people from traditional agriculture is less based on a perceived justification of taming the savage (Gasteyer and Flora, 2000) and more on a conviction that traditional agriculture does not have the financial promise that other land uses have, such as mining, reservoirs, plantations, and export crops. These changes in land use require changes in property rights that are referred to as development or as land grabs, depending on one's values and analytical approach (Kugelman and Levenstein, 2012). Because much of the land in traditional agriculture is untitled, the seemingly progressive move to title lands leads to massive displacement (Alden Wiley, 2012).

Many governments around the world are implementing what Brazilian economist Bresser-Pereira (2007, 2010) has named the New Developmentalism. That approach to modernization privileges generating financial capital through public–private partnerships (rather than relying mainly on the state under developmentalism, or the market, as under neoliberalism) in order to reach the other goals. But, as with neoliberal approaches, the new developmentalism is often accompanied by degradation of natural and human capital, disregard of cultural capital, and deteriorating social capital when the state does not act to check the market (Rodríguez-Garavito, 2011). Under this model, a new set of actors clustered around the financial sector – banks, both private and public; investment consultants and deal makers, etc. – have vested interests in changing land use (White and White, 2012).

Cultural hegemony – when the world view of a dominant group determines the actions of marginalized people – that discounts soil and traditional ways of caring for it came with the conquest, but continued well into the twentieth and even twenty-first century. It comes in part from the emphasis on short-term profit maximization as a major individual and household goal. Its impacts can be seen when Latin American smallholders turn to monocropping and high-input agriculture, which increases their financial risk and risk to soil

health. Often returning to ancestral ways of managing soils resolves risks to all the capitals.

Although there has been hegemonic pressures to use 'modern' agriculture, many of the processes that guided traditional practices have persisted and can be observed being implemented by smallholders in traditional communities around Latin America and elsewhere around the world (Wilken, 1987; Toledo, 1992; Rist and San Martin, 1993; Faust, 1998; WinklerPrins and Barrera-Bassols, 2004).

Political capital is the ability of a group, such as smallholders in an area, to translate their norms and values into standards that are then turned into rules and regulations and enforced. Those regulations often determine the distribution of resources, including access to natural resources, and how they are used.

In traditional agricultural communities, much land was controlled in common, with village leaders assigning land use on a year-by-year basis. In this system, women had access to land through traditional use rights. Privatizing land was thought to be a more efficient way of land management by modernizing elites. As land became titled and later sold, it was almost always titled in the name of the man in the household rather than the man and woman. The new private plots in the reformed areas and in new colonization and transmigration areas favored men's crops. There was seldom land left for the women's gardens, which were often vital for household nutrition and even survival. Women's collective production efforts were eliminated entirely. Often the animals that women would pasture, such as small ruminants, also were not allocated land for grazing. And in this process, communal ways of managing land, particularly through fallow, was eliminated.

Land reform was often necessary due to political unrest in response to inequality, the poverty induced by land concentration, and the lack of concern for the soil by absentee *latifundistas* (landlords). But in many places these reforms were unsuccessful in promoting rural well-being and ecosystem health. In part, the failure was due to superimposing new structures, rather than utilizing the traditional forms of social organization. Political decisions made from national capitals tended to impose a single model for the entire countryside, rather than considering the varied social and natural contexts.

In parts of Latin America, few export crops were planted until the era of land reform, beginning in the early 1960s. Most land reforms propagated during that period were intended to make land more productive, as measured through the market, not to redistribute land. Under the threat of expropriation, many large landowners shifted from extensive agricultural systems to more intensive ones, including soybeans, cotton, and even more sugarcane – all crops aimed for foreign markets. As a result, local populations, who had farmed the land as part of their usufruct rights, were displaced. Many moved to the cities, whereas others moved to less-desirable highland areas where they found that the traditional practices that worked well on flat ground tended to seriously erode hillside lands. Others moved to jungle and rain forest areas, with equally disastrous results.

The diversity of agricultural activities in traditional smallholder systems constitutes a livelihood strategy for many traditional agricultural communities, where the scarcity of agricultural land is a major limiting factor. Genetic conservation *in situ*, from the point of view of smallholders, guarantees at least minimal food security and guarantees that the household can obtain food without going to market, although they acknowledge the importance of markets in their overall strategy (Cuba *et al.*, 2006). In smallholder households, expenditure reduction, which is aided when soil quality is maintained, is often preferred over income increases, as the volatility of markets has been experienced by many smallholders in rural development projects in earlier eras.

The need for financial capital for purchased inputs, food, clothing, school, and taxes has encouraged many members of smallholder households to migrate to engage in wage labor. Such immigration may be long term or circular (Flora, 2006). Because such migration streams are predominantly of men, this leaves women with the agricultural tasks, leaving little or no labor for communal work that contributes to soil retention and fertility (Collins, 1988).

Land Grabs, Traditional Agriculture, and Culture

Increasingly, land is taken from smallholders and export crops, such as palm oil, are planted. The impacts are felt differentially by men and women. Men often see themselves as benefitting from the wage labor that comes on a seasonal basis, whereas women lose their opportunities to use traditional agriculture to provide for their households. These communities' experience of coercion, exploitation, intimidation, consent, and resistance is highly gendered, as women are more affected – and often more willing to resist – than are men (White and White, 2012). Land is being shifted from communal or smallholder ownership to governments and corporations, both national and international as part of the new developmentalism (German *et al.*, 2013).

Although 'modernizing' land tenure laws privatized some smallholdings in Africa and Asia (Alden Wiley, 2012), generally land held in common makes it extremely difficult to establish exact limits that meet surveyors' standards, although all in the community know what the limits are by natural indicators, such as trees, rivers, and rock formations. This makes defense of these communal lands almost impossible (Silva Castañeda, 2012).

The magnitude of this current wave of land deals is unprecedented: A World Bank (2010) study of 464 projects found land deals accounting for 46.6 million ha in 203 projects in 81 countries, with information on areas unavailable in the rest. This has increased substantially, since then, as countries see the possibility of public–private partnerships around resource extraction as good ways to enhance the public treasury and provide subsidies to the poor, including the poor that are displaced (German *et al.*, 2013).

Although there is much community protest and attempts to block projects, such as mining and dams, and protect traditional agriculture and cultures, these protests are generally ineffectual (Behrman *et al.*, 2012). Smallholders are pushed off the land and seek new areas to set up farming. Those areas are often marginal, and the practices brought, such as burning forests and turning them into pasture, further degrades the soil

and sets in motion a pattern of permanent migration that harms both natural and social capital.

The impact on transhuman cultures, such as the Sami in northern Scandinavia and Russia (Minority Rights Group International, 2012), or the Mapuche in southern Argentina and Chile (Bendini, 2001), is enormous. The link between the animals and the land needed for them to graze from season to season sets up conflicts with those who do not share their culture.

Conservation Land Grabs

Often conservation is used as the mechanism of separating ethnic groups from traditional agriculture – and their land (Chatty and Colchester, 2002). For example, in Belize the government informed the Mopan Maya that they were destroying the forest through their swidden agriculture (which they had used for thousands of years) and needed to vacate the forest. The targeted area has been referred to as the 'cultural hearth' of Mopan Maya (Wilk, 1997). The Maya, whose collective title to the land was affirmed by Belize's Supreme Court but still not recognized by the government of Belize, replied that they had used the system for thousands of years and the forest was flourishing. The Belize government denied their claims.

Sophisticated longitudinal analysis by scientists from the Ohio State University supported the Mayans: they were not decreasing forest cover, as they left ample time for regrowth. However, that did not stop the plan of removal of the Maya from their land, their agriculture, and their culture that included living with the land for a long time horizon (Wainwright *et al.*, 2013).

The government of Belize did not reveal the pending public–private partnership with a major logging company to use that same land (Servindi, 2013). It appears that the 'conservation' rhetoric against the Mopan Maya worked to allow the Belize government to change land use by finessing 'prior consultation,' a key concern for the Organization of American States' InterAmerican Commission on Human Rights (OAS/CIDH, 2004, 2009).

As Maasai leader Martin Sanin'o put in the 2004 World Conservation Congress, "We were the original conservationist. We don't want to be like you. We want you to be like us. We are here to change your minds. You cannot accomplish conservation without us." Over one hundred thousand Maasi 'conservation refugee' have been displaced from southern Kenya and the Serengeti Plains of Tanzania (Dowie, 2005).

Using Culture to Defend Traditional Agriculture

Culture determines what human groups declare to be 'fair' and 'just.' Many traditional societies are being deprived of their culture as they are removed from the land that sustained them for generations. Worldwide indigenous groups are responding to that removal by protesting and blocking attempts to drastically change their landscape and thus their culture.

Some of the movements defending indigenous lands and water as the basis for traditional agriculture and culture has received international attention, such as the case of Rio Blanco in Honduras. The Honduran-owned and foreign-financed company has been attempting to build a dam on the sacred Gualcarque River in the Lenca community of Rio Blanco. Community members have blocked the road against the company, thwarting the dam's construction, for more than 5 months. While the leaders of the movement against the dam are in prison, the company destroyed fields of corn, beans, coffee, and bananas (Bell and Fields, 2013). In the Philippines, indigenous people in Palawan united to demand a moratorium on the expansion of oil palm. As in the many cases, the pressures to expand come from the government in the form of public–private partnerships (Colchester *et al.*, 2006).

The movement among smallholders and indigenous people supporting *vivir bien* or *buen vivir* (living well) is an important reaffirmation of precolonial values and modern rights and responsibilities that support such positive change (Plataforma de co-partes de tierra de hombres, 2013). It has gained political saliency in Bolivia, where on 15 October 2012, the government passed Law 33, Law of the Framework of Mother Earth and Integrated Development to live well. The goal of the law and the movements promoted it to once again unite cultural capital, earth, and way by guaranteeing the continuity of the regenerative capacity of the components and system of life of Mother Earth, recuperating and strengthening local and ancestral knowledge, recognizing the complementarity of rights, obligations, and responsibilities (Delgado Burgoa, 2013).

Conclusions

Culture has linked humans to their environment for millennia. Agriculture and herding required that attention be paid to land and water, which were in turn honored as sacred and needed human attention, just as humans needed water, land, and animals to survive. Modernization has broken that link, sometimes by willfully destroying cultures in the name of civilization, but more often in order to get access to the natural resources the culture honored. Resistance to the loss of land and water is now being led by a call to return to cultures of solidarity with one's community and the Earth. Although there is little chance to return to traditional agriculture in many places, the link between traditional agriculture and cultures can provide alternatives in an increasingly changing environment.

Soil: Carbon Sequestration in Agricultural Systems

K Paustian, Colorado State University, Fort Collins, CO, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Greenhouse gases (GHG) Trace gases found in the atmosphere that absorb and emit infrared radiation, resulting in the greenhouse effect. These gases include naturally occurring gases, such as carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), water vapor (H_2O), and ozone (O_3), and several man-made gases, such as chlorofluorocarbons (CFCs), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6).

Histosols Soils that contain more than 12–20% organic C (depending on clay content), which are formed under inundated conditions in which minimal decomposition of plant residues occurs.

Leakage In the context of GHG mitigation, leakage is the increase in GHG emissions that occurs outside the boundary of a mitigation project or program, due to the mitigation activities undertaken inside the project/program boundary.

Mean residence time The average time for which a defined entity of matter (e.g., type of atom or molecule) remains within a defined state (e.g., soil organic matter pool) under steady state conditions.

Mineral soils Soils in which the dry mass is made up predominantly of mineral particles. Any soils that are not classified as histosols are considered mineral soils.

No-till A method of soil management in which physical disturbance and mixing of soils is excluded or nearly excluded and seeds or plants are sown in a narrow slot opened in the soil. Herbicides or nontillage mechanical means are used for weed control.

Organic soils Soils with high organic matter content, with at least 12–20% (depending on clay content) organic C by mass, to a minimum of 20 cm depth. These soils are typically formed under inundated conditions in which minimal decomposition of plant residues occurs.

Permanence Refers to the longevity that CO_2 removals by sinks (in this instance in soils) can be maintained without being reemitted to the atmosphere and the relative risk of loss of the sink integrity.

Radiative forcing Externally imposed perturbations of the earth's radiative energy balance because of secular changes in factors such as concentrations of greenhouse gases and aerosols, changes in incident solar irradiance, and changes in the radiative energy absorbed by the earth's surface.

Introduction

The challenges in dealing with global climate change are by now widely recognized among scientists, policy makers, and much of the general public. However, the role of land management and agriculture in particular, in both helping to mitigate and adapting to climate change, is much less well known. Changes in the concentration of greenhouse gases (GHGs) (e.g., carbon dioxide, CO_2; methane, CH_4; and nitrous oxide, N_2O) in the earth's atmosphere, which affect the net energy retained from the sun (referred to as radiative forcing), are the primary drivers of contemporary (and near future) climate change, and the use of fossil fuel is the dominant source of GHG emissions. What is less widely known – certainly by the general public – is that land-use activities currently account for approximately one-third of the human-induced warming from GHG increases (IPCC, 2007). Much of those land-use activities are directly or indirectly linked to agriculture and include multiple sources and different gases, for example, CO_2 emissions from deforestation and vegetation removal from ecosystems converted into agricultural use; CO_2, CH_4, and N_2O from managed soils; CO_2, CH_4, and N_2O from biomass, grassland, and crop residue burning; CH_4 and N_2O emissions from livestock husbandry; and a number of other minor sources (IPCC, 2007). Thus, agriculture has an important role to play in helping reduce these emissions and contribute to mitigation of GHG increases in the atmosphere.

One of the ways in which agriculture can contribute to GHG and climate change mitigation is through a process commonly referred to as carbon (C) sequestration. Broadly speaking, and in the context of GHG mitigation, carbon sequestration entails removing CO_2 from the atmosphere and storing it elsewhere, thus reducing the concentration of atmospheric CO_2 and its contribution to radiative forcing. A variety of pathways for carbon sequestration exist, including capturing CO_2 from large point source emissions and injecting it into deep geologic formations (known as carbon capture and storage) as well as enhancing natural biotic uptake of CO_2 by plants and then retaining more of that fixed C in biotic sinks or 'pools' including vegetation and soils. This latter process, taking advantage of the uptake of CO_2 from the atmosphere by plant photosynthesis and then increasing the storage of that fixed carbon in the soil, is referred to as soil C sequestration. This article focuses specifically on soil carbon sequestration on land managed for agricultural use, i.e., croplands and grazed grasslands.

In this article, basic principles and controlling mechanisms involved in soil carbon sequestration are presented, along with key concepts such as soil carbon equilibrium, saturation, and mean residence time. This is followed by a discussion of the agricultural practices that can be employed to increase soil C sequestration and an overview of the rates and amounts of soil C sequestration associated with different management practices, derived from long-term field experiments and other analyses. The article is then concluded by a section on science

 doi:10.1016/B978-0-444-52512-3.00093-0

and policy-related issues that have a bearing on the successful implementation of soil carbon sequestration as a GHG mitigation option.

Basics of Soil Carbon Sequestration

Globally, soils contain approximately 1500 Pg of organic C to a depth of 1 m (Batjes, 1996); of this total, approximately 45% is found in soils under agricultural use (~130 Pg C in croplands and 550 Pg C in grassland used for grazing; IPCC, 2000). In most cases, cropland soils are depleted in C relative to the native ecosystems (e.g., forest and grasslands) from which they were derived, largely due to the legacy of historical land use, including reduced net primary production, intensive soil disturbance, erosion, and export of crop residues as contributing factors (Paustian *et al.*, 1997a,b). It is estimated that cropland land use has reduced C stocks in the topsoil by 30–50% relative to their native condition (Davidson and Ackermann, 1993; Mann, 1986). In contrast, grassland soils managed for grazing may or may not have suffered C losses relative to their native state, depending on how they have been managed. In general, grassland soils that have been overgrazed and poorly managed are likely to be depleted in soil C, whereas well-managed grasslands may have C stocks equal to or exceeding their original native condition (Conant and Paustian, 2002a; Ogle *et al.*, 2004).

The carbon content of agricultural soils varies considerably as a function of climate, soil texture, drainage, and other biophysical factors. Most agricultural soils fall into a range of <0.5–5% C by mass in the top 10–20 cm, and the C content usually decreases sharply with depth. Although the highest concentration and most dynamic C stocks are found in the top 20–30 cm of the soil, significant amounts of soil organic carbon (SOC) can be found through the full depth of the root zone and below. Soils that have developed under restricted drainage (and therefore prone to waterlogging) can have much higher C contents, due to the reduced decomposition of plant litter under anoxic conditions. Soils in which much of the total mass consists of organic matter (i.e., peat and muck soils) comprise a special class of soils referred to as histosols and can contain very large amounts of C, in some cases up to several meters in depth. Although histosols are used as both cropland and grazing land, the vast majority of agricultural lands are on the so-called mineral soils in which organic C makes up a few percent of the total soil mass. Finally, in addition to C in organic forms, some soils contain significant amounts of inorganic C in the form of carbonate minerals (typically Ca/$MgCO_3$). Soils with high inorganic carbon contents include those formed from carbonate-containing parent material (e.g., limestone) as well as soils in arid and semiarid environments in which secondary pedogenic carbonates (e.g., caliche) are formed from the reaction of bicarbonate (derived from CO_2 in the soil) with base cations, which can then be precipitated in subsoil layers (Nordt *et al.*, 2000). However, in most cases changes in inorganic C stocks are slow and are not amenable to traditional soil management practices. Thus, further discussion of soil C sequestration in this article is restricted to organic C stocks.

The organic carbon content of soils is mainly governed by the balance between the emissions of CO_2 from decomposition processes (i.e., heterotrophic soil respiration) and the amount of carbon added to soils as plant residues and manures. Other processes such as leaching of dissolved organic C can affect the soil C balance, but in most soils leaching is a minor or insignificant C-loss process. Soil erosion can also have a significant impact on C stocks at a given location, by removing soil mass (including associated organic matter) from the soil surface. However, erosion is primarily a transport process so that materials removed from one area are subsequently deposited elsewhere. Thus, whether soil erosion contributes to a net emission of CO_2 to the atmosphere (a source) or it represents a C sink through the deposition and burial of C-rich sediments depends on landscape level dynamics of erosion and deposition (van Oost *et al.*, 2007). Although minimizing erosion is an important agricultural management objective, given the uncertainty about erosion impacts on soil C stocks at landscape and regional scales (Harden *et al.*, 2008), subsequent discussion of management impacts on soil C are made under the assumption of negligible soil erosion rates.

Given that soil C stocks are the result of a dynamic balance of C inputs and losses, increased SOC stocks can be achieved by increasing C inputs to soils and decreasing the specific rate of decomposition of organic matter already in the soil. Conversely, decreasing C additions and increasing the specific rate of decay will decrease soil C stocks. Over time, in the absence of major disturbances or changes in climate, soil C stocks tend toward an equilibrium in which the rate of C additions to soil and the rate of C losses from soil are approximately equal and soil C stocks remain roughly constant. The fundamental reason for this equilibrium behavior of soil organic matter is that decomposition rates for a given soil tend to be proportional to the amount of organic matter that is available for decomposition by soil organisms. This proportional relationship between decomposition rates and the amount of decomposable organic matter is referred to as first-order kinetics.

This simplified soil C balance can be shown as,

$$dC/dt = I - kC \quad [1]$$

in which the rate of soil C change (dC/dt) is given by the difference between the rate of C addition (I) and the rate of C loss via decomposition (kC), where k is the specific rate of decomposition and C is carbon content of the soil. The rate of C addition (I) is closely related to plant productivity and plant dry matter partitioning (i.e., between roots, leaves, fruits, etc.), which, in turn, are largely a function of climate, vegetation type, and soil fertility and water relationships. Similarly k, the specific decomposition rate, is influenced by climate and soil characteristics that determine the activity rate of decomposing organisms in soil.

In a young developing soil with low organic matter contents, 'I' initially exceeds 'kC' and hence SOC levels (C) initially increase, but as SOC accumulates, losses through decomposition rise and the SOC content eventually plateaus at a level where C additions are offset by decomposition losses and the rate of change equals 0, viz.,

$$dC/dt = 0 = I - kC \quad [2]$$

$$I = kC$$
$$C^* = I/k \quad [3]$$

where C^* is the equilibrium (or 'steady state') SOC level. Another useful concept is that of the mean residence time (MRT), which at steady state is defined as $MRT = 1/k$ and represents the average duration of C atoms in the SOC pool. From this simple model of the soil C balance, it is readily apparent that the equilibrium SOC level is directly proportional to the C input rate and inversely proportional to the specific decomposition rate. Most operational models of soil C dynamics conceptualize soil organic matter not as a single homogeneous entity (as implied in eqn [1]), but rather as a number of fractions or pools that vary distinctly in their relative rates of decay. However, it can be shown that even for models with multiple pools, provided that individual pools decay according to first-order kinetics, the overall equilibrium relationship shown in eqn [3] still holds (Paustian *et al.*, 1997a).

From eqn [3], it is clear that for a mature soil at an equilibrium SOC level, either an increase in the rate of C input or a decrease in the specific rate of SOC decay will provoke an increase to a new higher equilibrium SOC level. However, the rate of increase will be finite and within a few decades (depending on the SOC MRT) SOC levels will approach the new equilibrium level and the rate of change will go toward zero. **Figure 1** shows an idealized time history of SOC stocks, beginning with a substantial initial loss of C following conversion of a native ecosystem to annually cropped land, with a subsequent trend over time toward a lower equilibrium carbon level. Adoption of improved management practices on cropland can increase SOC stocks toward new equilibrium levels depending on the attributes of those systems.

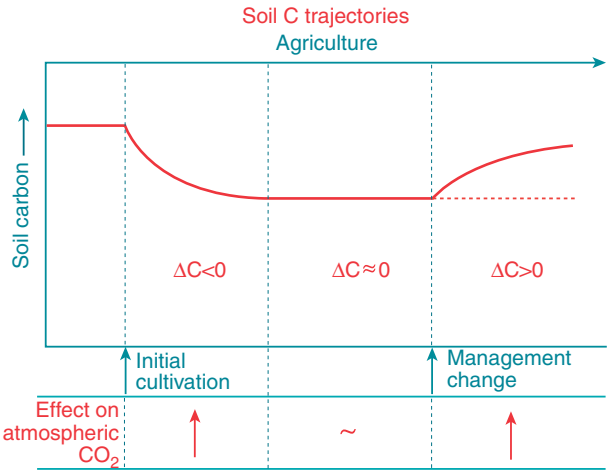

Figure 1 Idealized changes in soil organic carbon (SOC) over time as a function of ecosystem management. Conversion of native ecosystems to annual cropland leads to an initial loss of SOC (with net CO_2 emissions going to the atmosphere) that eventually tends toward new equilibrium where the net exchange of CO_2 with the atmosphere is near zero. Adoption of management practices that promote C sequestration results in an increase in SOC stocks with a net uptake of CO_2 from the atmosphere. Under the new practice, SOC stocks will again tend toward new equilibrium so that the rate of net CO_2 uptake diminishes over time. Reprinted with permission from Council for Agricultural Science and Technology (CAST), 2011. Carbon Sequestration and Greenhouse Gas Fluxes in Agriculture: Challenges and Opportunities. CAST Task Force Report 142. Ames, Iowa: CAST.

One implication of this model of soil C balance is that as C inputs increase, SOC stocks at equilibrium increase in direct proportion. Although there is good evidence that many agricultural soils exhibit this behavior over a limited range of C input levels (Paustian *et al.*, 1997b; Huggins *et al.*, 1998), a model assuming first-order kinetics implies that there is no upper limit to SOC storage and that stocks can always be increased by further increasing input rates (I; eqn [3]; see **Figures 2(a)** and **(b)**). Several lines of evidence suggest that there is an effective upper limit for the amount of SOC that can be stored in mineral soils, and the concept of soil C sequestration has been proposed as a modifier of the first-order model (Hassink and Whitmore, 1997; Six *et al.*, 2002). It is widely recognized that one of the main ways in which a portion of soil organic matter can persist for very long periods (centuries to millennia) is through interactions with soil mineral particles, in which organic matter bound on clay mineral surfaces and encapsulated within stabile microaggregates may be largely protected from decomposition by soil microorganisms (von Lützow *et al.*, 2006). As there is a finite amount of mineral surface area for a given soil, there would also be a limit to the amount of organic matter that could be physically protected against decomposition, and above this 'saturation limit' additional organic matter inputs would be subject to rapid decomposition and would be released as CO_2 (Six *et al.*, 2002; Stewart *et al.*, 2007; **Figures 2(c)** and **(d)**). The amount and type of clay minerals determine the amount of surface area and binding capacity for organic materials and thus soil texture and mineralogy are major determinants of the soil saturation capacity. Several recent experiments support this revised model of SOC balance (Stewart *et al.*, 2008; Chung *et al.*, 2010; Huang *et al.*, 2012; O'Brien and Jastrow, 2013).

The implications of saturation for soil C sequestration as a CO_2 mitigation strategy is that the soils (layers) which already have high organic matter contents may not be responsive to practices designed to further increase SOC stocks. Conversely, soils with C contents well below saturation (i.e., a large saturation deficit) will have greater capacity to stabilize more organic matter (**Figure 2(d)**) in SOC pools having long residence times and will show the greatest impacts of C-sequestering practices. Finally, it should be noted that this saturation concept applies to mineral soils only. For organic soils (i.e., histosols), decomposition dynamics are dominated by limited aeration due to a high and persistent water table that inhibits oxygen diffusion into the soil. Thus, SOC storage capacity under these conditions will be limited mainly by the depths to which organic matter can accumulate in the saturated zone, which is mainly controlled by underlying topography and hydrology.

Practices to Promote Soil Carbon Sequestration

As discussed in Section Basics of Soil Carbon Sequestration, many agricultural soils have lost a substantial portion of their original carbon stocks following conversion from native

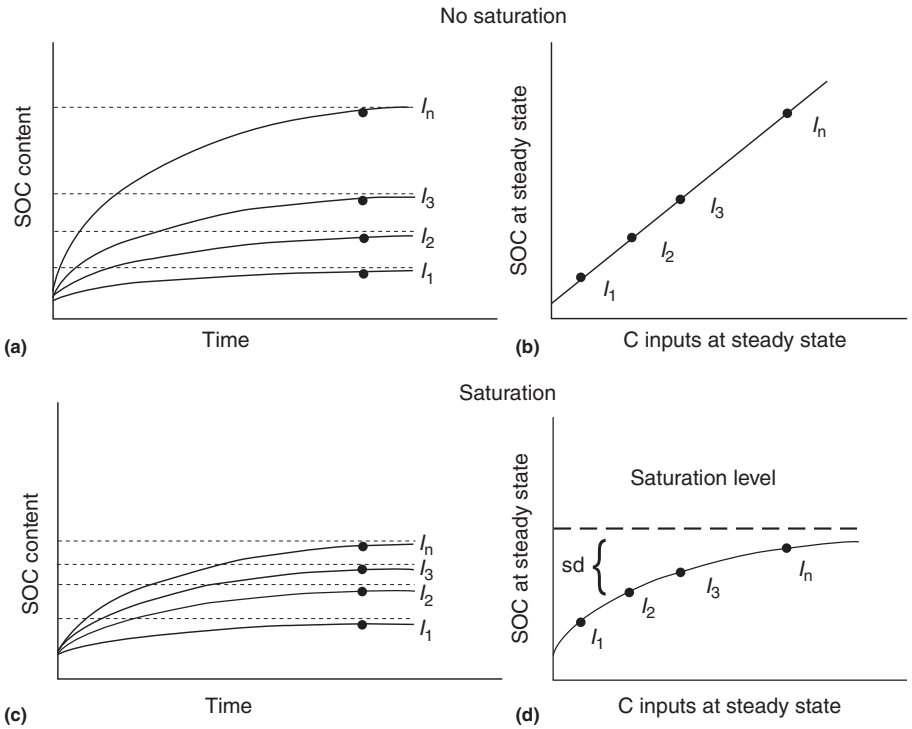

Figure 2 Illustration of differences in C dynamics and effects of C input rate on equilibrium soil organic carbon (SOC) stocks. Assuming first-order kinetics, increases in C input rates cause an increase over time in SOC stocks (a) toward a new equilibrium state, where equilibrium (i.e., steady state) SOC stocks are proportional to C input rate (b). Under saturation kinetics, increases in C input act to increase SOC stocks that also tend toward a new steady state over time (c), but the increase in the steady state SOC per unit of C input decreases as SOC stocks approach a saturation limit (d). The difference between SOC stocks and the maximum level at saturation is termed the saturation deficit (see (d)). Reprinted with permission from Figure 1 in Stewart, C.E., Paustian, K., Conant, R.T., Plante, A.F., Six, J., 2007. Soil carbon saturation: Concept, evidence and evaluation. Biogeochemistry 86, 19–31, with permission from Springer Science + Business Media B.V.

ecosystems. Land managed for annual crops in particular tends to be depleted in SOC as a consequence of historical land management practices. There are a number of different reasons for the loss of SOC following conversion to cropland. First, perennial native vegetation, which typically has a high fraction of C allocated below ground, was replaced by annual crops that were bred for maximum aboveground production and harvest offtake, thus minimizing crop residue return. Secondly, intensive soil tillage practices were typically used for weed control and for preparing a uniform seedbed. Conventional intensive soil tillage tends to break down soil structure and stimulates organic matter mineralization. In other cases, artificial drainage of wet soils (particularly histosols) and liming of acid soils, in order to improve conditions for annual crop production, resulted in accelerated organic matter mineralization, depleting SOC stocks. In contrast, agricultural lands managed for grazing (pasture and rangeland) are less likely to have a large SOC deficit relative to their native state, given the maintenance of perennial grass-dominated vegetation and thus high C allocation to roots and the lack of tillage disturbance. However, substantial management-induced C losses can occur, especially with overgrazing or poor grazing management in which plant production is degraded, thereby reducing C inputs from plant residues. Also, pastures established on organic (e.g., peat) soils typically involve drainage and other practices (e.g., liming and fertilization) that can greatly stimulate decomposition rates resulting in large decreases in SOC stocks.

Given these impacts of past conventional management practices, there is a clear potential to recover previously lost carbon with the adoption of improved practices. In many cases, SOC stocks under native vegetation do not represent a maximum or saturation limit for SOC contents, so at least theoretically it may be possible to sequester more SOC than under conditions of the native ecosystem.

The main practices that can contribute to an increase in carbon stocks in soils are well known from numerous field experiments and comparative field observations. Table 1 lists several classes of practices, classified according to their main mode of action in either increasing C inputs or reducing C losses emissions.

Increased Productivity and Residue Retention

Numerous long-term field experiments in which crop rotation or residue retention is the main treatment variable show a roughly linear relationship between the rate of C return in residues and changes in SOC stocks (e.g., Paustian *et al.*, 1997a; Huggins *et al.*, 1998). Annual crops that produce large amounts of residues, such as corn and sorghum, typically result in higher soil carbon levels than many other crops.

Table 1 Agricultural management actions that can increase organic carbon storage and promote a net removal of CO_2 from the atmosphere

Management practice	*Increased C inputs*	*Reduced C losses*
Increased productivity and residue retention	✓	
Conversion to perennial grasses and legumes	✓	✓
Manure and compost addition	✓	
Biochar addition	✓	
No-tillage and other conservation tillage		✓
Rewetting organic (i.e., peat and muck) soils		✓
Improved grazing land management	✓	

For example, long-term experiments at two sites in Ohio (Dick *et al.*, 1998) show approximately 10 Mg C ha^{-1} more soil carbon after 30 years under continuous corn crops or with corn–oat–hay rotations than in the conventional corn–soybean rotations, equal to an average gain of 0.3 Mg C ha^{-1} $year^{-1}$. Soybeans typically produce approximately one-third as much residue as corn (and also much less than hay crops), and this lower C input rate accounts for the lower SOC levels.

Conventional annual crop production in temperate climates often entails crop production only over the main growing season (summer) such that the soil is bare for half or more of the year (during the winter fallow period). If favorable moisture and temperature conditions exist, winter cover crops (e.g., annual grasses, legumes, and root crops) can be grown outside of the main cropping season, supplying additional residue inputs. Another option to both lengthen the total vegetated period during a crop rotation and incorporate crops that have higher C inputs is to combine annual crops with short-duration (2–4 year) perennial grasses and legumes that are used for forage production. Such mixed annual/perennial crop rotations were the dominant practice on cropland in much of Europe and North America before the widespread use of chemical fertilizers and the replacement of animal traction by machinery.

Similarly, in many semiarid regions (e.g., Great Plains of the United States and Canada, parts of the Australian wheat belt, and parts of Europe, Africa, and the Middle East), cereals may be grown in a 'summer fallow' rotation in which one crop (e.g., winter wheat) is grown only every other year. This is primarily done to store additional soil water during the long fallow period to help ensure a successful grain harvest from the planted crop; however, it results in the soil being bare for as much as 18 months during a 2-year period. However, by using no-till practices (see Section No-Till and Conservation Tillage Practices) and more drought-resistant crops, it is possible to add additional crops to the rotation and substantially reduce or eliminate the bare fallow period, thus increasing the amount of plant residues added to soil (Peterson *et al.*, 1998; Alvaro-Fuentes *et al.*, 2008).

Several reviews have been made of long-term field experiments with different crop treatments that relate to the amount of crop residues returned to the soil. In a majority of field studies reviewed by Ogle *et al.* (2005), rotations with high C inputs (i.e., use of winter cover crops, green manures, irrigation, high residue crop varieties, or annual crop rotations that have one or more years of hay) increased SOC storage relative to conventional crop rotations (e.g., continuous cereals) by 7–11% over a 20-year period. In a more recent review of US studies (Eagle *et al.*, 2012), the authors reported average C sequestration rates of 0.27 Mg C ha^{-1} $year^{-1}$ for winter cover crops and 0.16 Mg C ha^{-1} $year^{-1}$ for more diversified crop rotations. Including perennial crops in the rotation and full conversion to perennial crops resulted in average sequestration rates of 0.16 and 0.62 Mg C ha^{-1} $year^{-1}$, respectively. In semiarid systems, intensifying crop rotations by eliminating or reducing summer fallow has been found to increase soil C stock when converting into no-till practices (Campbell *et al.*, 2005). It is likely that the key factor involved is the additional water storage occurring under no-till, enabling greater total crop production over the rotation and hence greater C inputs to the soil (Peterson *et al.*, 1998). The C sequestration potential of eliminating summer fallow in the United States and Canada has been estimated to be 0.1–0.2 Mg C ha^{-1} $year^{-1}$ (Eagle *et al.*, 2012).

In addition to altering or intensifying crop rotations, practices that promote the more efficient use of inputs, such as fertilizer and irrigation, will generally yield the best results for GHG mitigation (Paustian *et al.*, 1998). Efficiency in this context is defined as maximizing crop production per unit of input. Where fertilizer and irrigation inputs are used in excess, there is risk of increases in other GHG emissions, particularly nitrous oxide, which can offset part or all of the gains in soil carbon. Tailoring fertilizer and irrigation applications to match crop nitrogen demands, so that less nitrogen is left behind in the soil, can reduce nitrous oxide emissions while building soil carbon stocks. Efficient use of irrigation water will similarly reduce nitrogen losses, including nitrous oxide, and minimize CO_2 emissions from energy use for pumping while maintaining high yields and crop residue production.

Conversion of Annual Cropland to Perennial Grasses and Legumes

In some instances, marginal croplands that are susceptible to high erosion rates, flooding, or have otherwise unsuitable soils have been allowed to revert to natural vegetation or replanted to perennial vegetation as a soil conservation measure. Examples of land-use policies to set aside such marginal lands include the Conservation Reserve Program (CRP) in the United States and similar set-aside programs in other industrialized countries. In addition to governmental policies, reversion of annual cropland for wildlife conservation is being explored by private organizations (Ducks Unlimited, 2013). Such cropland set-asides can result in significant C sequestration

benefits, due to the greater root C inputs and elimination of soil tillage with conversion into perennial vegetation. Other practices involving small-scale land cover conversion, such as adding grass buffer strips along cropland field margins, can additionally sequester C by the perennial vegetation as well as trap sediment from agricultural runoff. In reviewing studies involving conversion of annual cropland to grassland as a conservation set-aside, Ogle *et al.* (2005) found a restoration of SOC levels ranging from 82 to 93% (for the top 30 cm) of native grassland levels after 20 years. A global literature review by Post and Kwon (2000) estimated average C sequestration rates for conversion of agricultural land into perennial forest and grassland at 0.34 and 0.33 Mg C ha^{-1} $year^{-1}$, respectively. Overall, conversions of cropland tended to yield somewhat higher SOC gains in subtropical compared with temperate regions. Studies of SOC accumulation rates on CRP land in the United States by Follet *et al.* (2001) yielded average increases of 0.9 Mg C ha^{-1} $year^{-1}$ (in the 0–20 cm depth). A more recent review of published studies on set-aside lands in the United States estimated an average C sequestration rate of 0.68 Mg C ha^{-1} $year^{-1}$ (Eagle *et al.*, 2012). The potential of set-aside land to sequester C greatly depends on the vegetation, former land use, soil type, and climate. Another important factor to consider is the duration of the set-aside practice. In many instances, set-asides are later returned to annual cropland use, and thus much of the soil C accumulated during the set-aside may be lost following reversion to annual cropping. Thus, permanent set-asides for conservation purposes are needed to preserve the C sequestration benefits over the long term.

Manure and Compost Addition

Soil organic matter typically increases much more with manure or compost additions than for an equivalent amount of C added as crop residues or green manure. As manure and compost consist of plant matter that has already been partially decomposed (i.e., in animal digestive tracts and subsequently in manure storage or composting systems), the residual organic matter decomposes more slowly than fresh plant material and thus promotes a greater increase SOC per unit of C addition (Paustian *et al.*, 1997b). Changes in SOC stocks from application of animal manure, and to a lesser degree compost, have been studied extensively in long-term field experiments (e.g., Paustian *et al.*, 1997a,b; Ogle *et al.*, 2005; Eagle *et al.*, 2012). In a global meta-analysis, Ogle *et al.* (2005) found that manure additions were among the crop management practices yielding the greatest increases in SOC, with an average increase of approximately 35% in SOC in the top 30 cm compared with reference cropping systems with no manure addition. Based on European studies, Freibauer *et al.* (2004) estimated an average rate of SOC increase of 0.4 Mg C ha^{-1} $year^{-1}$ with application of farmyard manure on cropland. One issue in considering organic amendments (manure and compost) as a soil carbon sequestration activity is that the organic matter in the manure often originates from off-site locations (i.e., as purchased livestock feed). Thus, a full net accounting of the impact of manure additions on soil C (and other GHGs) requires that the C 'cost' associated with the production of the livestock feed itself be included in the calculation (Smith and Powlson, 2000).

Biochar Addition

Biochar has received attention as a soil amendment for C sequestration that can also enhance soil fertility and crop productivity (Lehmann *et al.*, 2006; Lehmann, 2007; Verheijen *et al.*, 2009). Biochar is essentially the same substance as charcoal, but the term biochar is typically used to denote its intended use as a soil amendment rather than as a fuel (charcoal). Biochar is formed from the heating of biomass (300–1000 °C) in the absence of oxygen and is a coproduct of pyrolysis and gasification processes used to produce liquid and gaseous fuels. Biochar is the solid residue remaining in which O and H have been preferentially removed with the more volatile biomass components, and thus the residue consists of C-rich and highly aromatic molecules and ash (i.e., K, Ca, and Mg). In general, the higher the treatment temperature, the more the O and H are removed and the solid residual takes on more of a graphite-like structure that consists of sheets of hexagonally arranged carbon atoms (graphene). In addition to temperature, the duration of the heating as well as the properties of the original biomass contributes to chemical and physical variation of the biochar (Verheijen *et al.*, 2009).

Owing to its recalcitrant chemical structure, the graphene-like biochar molecules are not readily decomposed by microorganisms and thus can remain in soils for hundreds or thousands of years. Thus, biochar produced from renewable biomass stocks (or from waste biomass) as a coproduct of biofuel production offers a potential means to sequester large amounts of C in soils. Modern interest in biochar as a soil amendment stems from studies of prehistoric 'anthropomorphic' soils in the Amazon region – the so-called Terra Preta – which are believed to have been formed from additions of charcoal and various household waste and plant residues over many years (Glaser *et al.*, 2001). These soils are dark in color, rich in organic matter, and more fertile than the native highly weathered acidic soils. There is considerable interest and ongoing research on how biochar affects plant productivity and various soil properties (e.g., pH, water-holding capacity, cation exchange capacity, nitrogen dynamics, trace gas emissions, and microbial communities). Although much of the research to date suggests that biochar additions can be beneficial to many soils (particularly for old and highly weather acidic soils in tropical climates), the irreversible nature of biochar additions to soil has led to calls for more research to determine optimal amounts of biochar additions and how different types of biochar (i.e., type of plant material, heating temperature and duration, etc.) impact the plant–soil system. In addition, the economic and full life cycle implications of large-scale production and use of biochar in agricultural systems are just beginning to be assessed (Field *et al.*, 2013).

Rewetting of Organic Soils

Cultivated organic soils represent another land restoration opportunity. These lands are a significant source of agricultural CO_2 emissions with high rates up to 10–20 Mg C ha^{-1} $year^{-1}$

(Ogle *et al.*, 2005). Hence, wetland restoration may be a mitigation option. However, restored wetlands may emit methane, which would need to be considered in assessing the overall mitigation potential of wetland restoration.

No-Till and Conservation Tillage Practices

The use of no-till and other conservation tillage practices have been adopted increasingly over the past 20 years. No-tillage eliminates the turning and mixing of the soil by using herbicides for weed control and planting seed directly into the soil at the desired depth with no other soil disturbance. Typically, aboveground residues are left in place on the surface. Other so-called conservation tillage practices (e.g., mulch tillage and ridge tillage) still involve some physical disturbance of the soil with tillage implements, although to a shallower depth or less intense mixing of the soil compared with conventional tillage using a moldboard plow or deep-disk tillage.

It is well recognized that intensive soil tillage tends to accelerate organic matter decomposition – resulting in oxidation of carbon to CO_2 – by warming the soil, breaking up residues and soil aggregates, and placing surface residues into the moister environment within the soil (Reicosky *et al.*, 1995; Six *et al.*, 2000). Hence, reducing the frequency and intensity of this physical soil disturbance helps to preserve the natural soil structure and enhances the stabilization (i.e., decreased susceptibility to decomposition) of organic matter within soil aggregate structures (Denef *et al.*, 2004).

Several reviews of long-term field studies with varying tillage treatments have summarized findings on SOC sequestration rates following conversion to reduced or no-till. More consistent soil C sequestration rates are typically found for conversions to no-till than to reduced-till systems, probably reflecting the greater stabilization of organic matter with the near complete absence of mechanical disturbance with no-till (Six *et al.*, 2000; West and Post, 2002). Using a global dataset of 67 long-term agricultural experiments, West and Post (2002) reported SOC sequestration with adoption of no-till averaging 0.48 Mg C ha^{-1} $year^{-1}$ over a mean duration of 15 years. Ogle *et al.* (2005) analyzed data from 126 studies worldwide and estimated that soil carbon stocks in surface soil layers (to 30 cm depth) increased by an average of 10–20% over a 20-year time period under no-till compared with intensive tillage practices. The relative increases in SOC were higher under humid than dry climates and higher under tropical than temperate temperature regimes. For the Southeastern United States, Franzluebbers (2010) estimated SOC sequestration with conservation tillage at 0.45 Mg C ha^{-1} $year^{-1}$ and Johnson *et al.* (2005) found a similar average gain of 0.48 Mg C ha^{-1} $year^{-1}$ in the Central United States. Lower average rates have been reported for the Southwestern (0.30 Mg C ha^{-1} $year^{-1}$, Martens *et al.*, 2005) and Northwestern United States (0.27 Mg C ha^{-1} $year^{-1}$, Liebig *et al.*, 2005). For the entire United States, a recent review (Eagle *et al.*, 2012) estimated mean C sequestration rates of 0.3 Mg ha^{-1} $year^{-1}$ for conservation tillage and no-till systems, similar to earlier estimates by West and Marland (2002) for no-till systems in the United States (0.34 Mg ha^{-1} $year^{-1}$).

The impact of tillage practices on SOC stocks appears to depend heavily on climate (Ogle *et al.*, 2005; Six *et al.*, 2004) as well as soil type (Dumanski *et al.*, 1998) and initial soil organic C content (Franzluebbers, 2010). A lack of C sequestration following no-till adoption, or even C losses relative to intensive tillage, has also been reported for some cool, moist environments and on heavy textured soils (e.g., Angers and Eriksen-Hamel, 2007). Reduced rates of residue C inputs under no-till for corn and wheat, predominately in cooler, wetter regions (upper Midwest), may explain part of the reduced C sequestration performance of no-till under these conditions (Ogle *et al.*, 2012). Also, soils in cool, wet environments often have already high surface organic matter contents and thus may be closer to a C 'saturation level' and hence less of the residue added at the soil surface under no-till can be effectively stabilized (Stewart *et al.*, 2007; Gregorich *et al.*, 2009).

Improved Grazing Land Management

Permanent grasslands can maintain large SOC stocks due to several characteristics. Perennial grasses allocate a high proportion of photosynthetically fixed carbon below ground, maintain plant cover year-round, and promote formation of stable soil aggregates. However, the potential for increasing SOC stocks in grazing lands is highly dependent on past management and the extent to which plant productivity and carbon inputs can be enhanced through management improvements (Conant *et al.*, 2001). Grassland systems that have been degraded in the past or maintained under suboptimal management conditions are most conducive for sequestering additional carbon.

A commonly used differentiation of grazing land is between pastures and rangelands, where pastures are more intensively managed grazing lands, often with nonnative (introduced) plant species, located in mesic (humid and subhumid) environments, compared with rangelands that are more extensively managed, with predominantly native plant species, in semiarid and arid environments. These differences in climatic conditions and management intensity largely align with the type of management interventions that are possible to enhance SOC sequestration. Pasture systems with their higher productivity offer a diverse set of management options, for example, selection of improved grass species, overseeding with legumes, improved fertilizer management, water management, liming, and improved grazing systems. In contrast, most rangeland systems have relatively low plant productivity and therefore practices such as fertilization are unlikely to be financially viable. In rangelands, management activities are mostly restricted to manipulating grazing practices (density, duration, and timing of livestock grazing) and vegetation manipulations, such as burning and mechanical removal/control of woody shrubs.

Conant *et al.* (2001) summarized more than 115 studies of management effects on grassland SOC and estimated rates of C increase averaging between 0.1 and 3 Mg C ha^{-1} $year^{-1}$ for different management improvements. The highest rates occurred with introduction of deep-rooted African grasses in South American savannas (Fisher *et al.*, 1994), whereas most of the higher rates for temperate grasslands showed gains of approximately 1 Mg C ha^{-1} $year^{-1}$. Average rates of SOC

increase were approximately 0.3 Mg C ha^{-1} $year^{-1}$ for fertilization and improved grazing systems and approximately 0.7 Mg C ha^{-1} $year^{-1}$ for introduction of legumes.

Appropriate grazing strategies are important to maintain grassland health, productivity, and SOC stocks, although it is difficult to generalize the effects of stocking rates and grazing intensity across the great diversity of pasture/range systems. Overgrazing, where grassland productivity and plant cover are significantly diminished, generally decreases soil (and plant) C stocks (Ogle *et al.*, 2004), whereas low to moderate grazing intensities tend to promote higher C storage (Ogle *et al.*, 2004; Franzluebbers and Stuedemann, 2009), compared with either ungrazed or heavily grazed systems. More intensively managed grazing systems – often referred to as rotational grazing, mob grazing, or multipaddock grazing – can be effective by promoting efficient use of available forage while allowing an optimal 'rest and recovery' period for regrowth (Conant *et al.*, 2003). However, many whole-system grazing approaches are difficult to generalize because grazing practices are often site specific and involve a suite of different management activities. Some studies suggest that rotational grazing can increase soil C stocks in humid and subhumid environments (Conant *et al.*, 2003; Sanjari *et al.*, 2008; Teague *et al.*, 2010), relative to conventional continuous grazing. In tallgrass prairie systems in the United States, Teague *et al.* (2010) found that rotational grazing increased soil organic matter by 50% relative to heavy continuous grazing and 11% relative to light continuous grazing. However, in a review of grazing systems focusing mainly on semiarid rangelands in the United States, rotational grazing systems did not appear to significantly improve the grassland productivity, soil C stocks, or animal performance, relative to continuous grazing systems, at the same stocking rates (Derner and Hart, 2007; Briske *et al.*, 2011). In these systems, the dominant controls on soil C stocks, independent of grazing system, appear to be total animal stocking rate and precipitation (Derner and Schuman, 2007).

Overall Soil Carbon Sequestration Potential

A variety of estimates of soil C sequestration potential on agricultural lands have been made at national as well as global scales (e.g., Paustian *et al.*, 1998; IPCC, 2000; Lal, 2004; Smith *et al.*, 2007). These estimates build on regionally averaged gains in soil C for various management interventions and assumptions of the land area available for implementation and potential rates of adoption of C-sequestering practices. Such estimates are referred to as technical potentials in that they do not consider economic or policy constraints on the actual amounts of mitigation that might be achieved. Technical potentials can be regarded as a theoretical upper limit with present technologies in the absence of economic or other constraints on implementation. Thus, the expected mitigation potential that could realistically occur would be much lower.

Currently, the most comprehensive and spatially and temporary refined estimates of global soil C sequestration are those given in the Intergovernmental Panel on Climate Change fourth assessment report (IPCC, 2007; Smith *et al.*, 2007). The analysis stratifies global agricultural land area by economic/development zones as well as major climatic and land-use type. Their analysis also considers economic constraints on achievable mitigation by using regionally modeled marginal cost curves for implementing new practices and various levels of C offset pricing to estimate how much adoption of mitigation practices would be incentivized at a given monetary value for GHG reductions achieved (Figure 3).

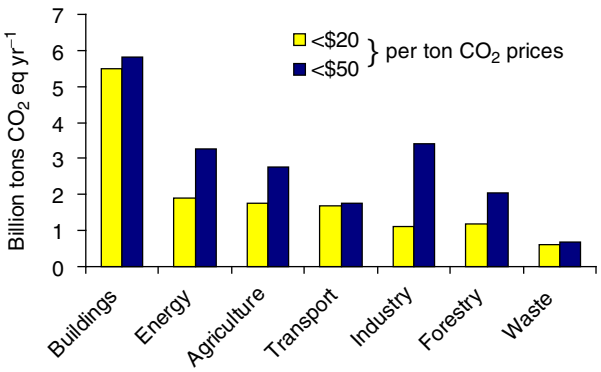

Figure 3 Estimates of potential GHG mitigation by major sectors of the global economy for two putative marginal carbon prices (<20 and <50 US$), reproduced with permission from Smith, P., Martino, D., Cai, Z., *et al.*, 2007. Greenhouse gas mitigation in agriculture. Philosophical Transactions of the Royal Society, B 363 (1492), 789–813. Estimates are in billion MT CO_2 equivalent per year. Estimates include mitigation for all gases (CO_2, CH_4, and N_2O) and emission sources but carbon sequestration constitutes ~90% of total mitigation potential for the agricultural sector (Smith *et al.*, 2007).

Although there are still many uncertainties with such an analysis, it provides a useful first approximation of what mitigation might be achieved through improved agricultural practices if a significant economic value were placed on emission reductions as part of mandatory GHG reduction policies. This analysis (Figure 3) also suggests that agricultural mitigation options have the potential to be a significant contributor to overall reductions in GHG emission as the agricultural potential in total is similar to the mitigation potential for other major sectors of the global economy.

Implementation of Soil Carbon Sequestration – Challenges and Opportunities

For soil carbon sequestration to become a significant GHG mitigation strategy, a number of technical and policy-related barriers need to be overcome. For the vast majority of agricultural soils, increasing and maintaining SOC stocks is a highly desirable objective for improved productivity and sustainability. Thus, some adoption of improved management practices that promote C sequestration will undoubtedly occur independent of climate change concerns. However, to qualify as a mitigation practice, actions need to be in addition to 'business as usual' activities (i.e., activities that would have taken place in the absence of mitigation policies). This principle is referred to as 'additionality' and it is a widely recognized concept for climate mitigation policies at both national and international levels. Thus, agricultural GHG mitigation, including soil C sequestration, will involve incentivizing farmers to adopt practices beyond what they might do anyway. There can be a variety of reasons – including economic,

technical, social, and cultural barriers – why farmers might not otherwise adopt C sequestering without additional incentives (Antle *et al.*, 2003). Incentives might come in the form of government payments or other support for adopting conservation practices. Another approach is to allow agricultural producers to generate the so-called carbon offsets, which then have value in a cap-and-trade emission reductions system. With a cap-and-trade policy, emissions from large industrial sources are subject to mandatory limits (caps) that then decrease over time. To comply with the specified emission reductions, industries that are subject to the cap either can undertake mitigation activities for the capped sources or may purchase unused emission allowances or offsets from elsewhere within the system, for example, from agricultural mitigation projects.

To date, soil C sequestration has not been included in many major GHG mitigation policies, such as the Kyoto Protocol and the Clean Development Mechanism (CDM). However, there is broader interest in including soil C sequestration as a part of future international agreements, in part because of the added benefits from encouraging soil improvements generally and helping to buffer vulnerable agriculture soils against climate change impacts (Smith and Olesen, 2010). In addition, outside of formal regulatory agreements, there is a growing voluntary market for GHG mitigation activities and several soil C sequestration projects have been initiated in which farmers and land owners can receive financial incentives to undertake improved management practices through the production and sale of C offsets for the voluntary market.

In the remainder of this chapter, a brief discussion is provided about some of the technical and policy-related issues with respect to soil C sequestration. Because GHG mitigation activities can span all sectors of the global economy and a wide variety of emission sources, any one mitigation strategy (including soil C sequestration) must be competitive with other mitigation actions. Thus, a key issue is providing confidence to policy makers and potential emission offset buyers that soil C sequestration from agricultural practices is 'real' (i.e., actually benefits the atmosphere), can be measured and verified, and that the emission reductions are long lasting ('permanent').

Quantifying Soil C Sequestration

Accurately quantifying changes in soil C stocks is the key to ensuring that C sequestration resulting from improved land use and management practices is real and verifiable. Compared with many other emission sources, for example, CO_2 emissions from fuel consumption, quantifying soil C stock changes is more complex and difficult. Soils differ from point emission sources in that emissions and sinks (C uptake) are distributed widely across a varying and heterogeneous landscape. In addition, soil C dynamics are driven by a complex and interacting set of factors, many of which vary at fine spatial scales. Thus, soil responses to the same set of practices can often vary significantly across the landscape and even within the same field (Paustian *et al.*, 2011). This makes accurate local-scale quantification of soil C stock changes, as for a specific mitigation project, challenging. Two main options are described: (1) direct measurements of C stock changes and (2) practice-based approaches using empirical or process-based models, although in practice a combination of the two options might also be used.

Direct measurement of soil carbon changes

Estimating the net flux of CO_2 between soils and the atmosphere can, in principle, be done with direct flux measurements, such as eddy covariance (Hollinger *et al.*, 2005). However, these techniques are largely confined to research applications and are not practical for routine measurement and monitoring of mitigation projects. Instead, the main direct measurement approach involves tracking changes in SOC stocks over time. This C-balance approach assumes that the primary C flows that affect SOC stocks are the addition of C from plant/animal residues (representing CO_2 uptake) and the losses of CO_2 via decomposition and mineralization of organic matter in the soil. Thus, measurement of SOC stock changes at the same location at two or more points in time, or measurements of contrasting management treatments (preferably in a randomized field experiment) that have been in place for a known period of time, can be used to estimate net CO_2 emissions or removals by soils.

Accurate methods to measure SOC content (i.e., g C g^{-1} soil) and soil bulk density (i.e., g soil cm^{-3} soil), which are the two values needed to compute SOC stocks on an area basis and to a defined depth, have been developed and routinely applied for many decades. Automated dry combustion soil C analyzers are highly accurate and currently constitute the 'gold standard' for measuring C concentration in soils. Mid- and near-infrared spectroscopy (and other spectroscopic methods) are being used more widely as a way to reduce analysis costs and increase sample throughput (Shepherd *et al.*, 2003; Brown *et al.*, 2006; Janik *et al.*, 2007), although they require careful calibration for different soil types to attain high accuracy and precision. Bulk density is easily measured gravimetrically from a known sample volume but requires care in sampling and handling (e.g., avoiding compaction).

Thus, the challenge in measuring SOC stock changes is not in the measurement technology per se but rather in designing an efficient and cost-effective sampling regime. The spatial variability of SOC is often high (Robertson *et al.*, 1997) and the rate of C stock change is typically low relative to the amount of C already present in the soil; thus, there is a low 'signal-to-noise' ratio. Hence, a 5–10-years period between measurements is typically needed to adequately detect the cumulative change (Conant and Paustian, 2002b; Smith, 2004). Depending on the degree of spatial heterogeneity and the amount of change relative to the background level, detecting significant changes at field scales can require a relatively large number (e.g., 15–100) of samples (Garten and Wullschleger, 1999). However, sampling designs configured for precisely relocatable points for repeated measurement over time (e.g., Conant *et al.*, 2003; Lark, 2009; Spencer *et al.*, 2011) can reduce sample requirements compared with simple random or stratified random sampling designs. Because the sample size requirements (per unit area) decrease greatly as the area of inference increases in size (Conant and Paustian, 2002b), direct measurements – although expensive – can be feasible for large project areas (Mooney *et al.*, 2004).

Model-based approaches

Models provide a means to integrate the effects of different land-use and management practices, as well as soil and climate effects, on SOC stocks. The models use data on land management practices, i.e., 'activity data,' together with information on environmental variables, such as climate and soil type, to predict soil C stocks and C stock changes for project-level accounting (Paustian *et al.*, 2011). As part of an activity or 'practice-based' approach, models provide a means of estimating outcomes (i.e., C stock change) for specified actions (i.e., adoption of prescribed conservation practices). In a broad sense, models of SOC change can be characterized as empirical models, which are based on statistical relationships estimated from field measurements, and process-based models, in which the model algorithms are based on more basic scientific principles as well as parameterization and testing against field measurements. Most process-based models strive to achieve a more general description of the processes and controls on SOC dynamics in order to better represent the complex interactions between these controls. A key requirement for model-based approaches is that they have demonstrated acceptable predictive capacity for the conditions for which they are being applied, typically by validation against long-term field experiment data.

A variety of process-based models (e.g., Century (Parton *et al.*, 1994), DayCent (Del Grosso *et al.*, 2002), DNDC (Li *et al.*, 1992), EPIC (Williams, 1995), and RothC (Coleman and Jenkinson, 1996), among others) that were developed originally as research tools have been utilized to varying degrees for soil C and GHG inventory and accounting purposes. Further discussion of the details of these and other models of soil C dynamics is beyond the scope of this article. Recent reviews of these model-based approaches for soil C accounting can be found in Denef *et al.* (2012) and Paustian *et al.* (2011).

One limitation of process-based model approaches for quantifying soil C dynamics is that most of these models – because they were originally designed for research purposes – are difficult to use without specialized training. To make such models more accessible to project managers, developers, and natural resource management personnel – as well as farmers themselves – several soil C and GHG estimation support tools have been developed in recent years. Reviews and information about obtaining and using user-friendly calculators for estimating soil C sequestration and GHG emissions from agriculture are provided by Denef *et al.* (2012).

Other Policy-Related Issues Relevant to Soil C Sequestration

Full GHG accounting

The use of soils as a C sink for removal of CO_2 from the atmosphere is only one of a number of processes and GHG gas species that are affected by agricultural management practices. As detailed elsewhere in this volume, soils are also sources of two other biogenic GHGs, namely, nitrous oxide (N_2O) and methane (CH_4). Thus, an important consideration when promoting soil C sequestration for GHG mitigation is the various interactions between soil C dynamics and processes involved in N_2O and CH_4 emissions. In some cases management practices that could increase soil C storage could have impacts on these other emission processes, such that the benefits of additional CO_2 removal and storage are reduced or eliminated by increased emissions of these other gases. Examples of such counteracting outcomes include increased N fertilizer or manure additions that could not only induce soil C increases but also stimulate N_2O emissions; similarly, increased straw residue retention in flooded rice systems could not only benefit soil C storage but also promote higher soil CH_4 emissions. Because soil C and N cycles are closely linked, there are numerous interactions of importance for the net greenhouse balance of a particular management system. Hence, design and implementation of soil C sequestration projects should consider the impacts of any practices on all three gases and have the capability to perform full net GHG accounting.

Permanence

The issue of permanence in the context of GHG mitigation is specifically applicable to C sinks. Current mitigation policies define reductions in emissions as permanent in the sense that the act of reducing emissions in the present should not increase the risk for increased emissions at some point in the future. For carbon sinks, whereby actions are taken to remove CO_2 from the atmosphere and store it elsewhere (e.g., in soils), there is a risk that the stored C could be reemitted at a later time if the integrity of the C sink is compromised. Thus, the benefits to the atmosphere would be much less as CO_2 was only temporarily removed. Because C in soil organic matter (as well as C in biomass and other biotic-derived pools) is part of an active C cycle with the atmosphere, these C stocks are not permanent in a strict sense. However, if a C sink (i.e., an increase in SOC storage) can be maintained over a long period of time, then the net removal of CO_2 from the atmosphere can meet the permanence requirement. Thus, for implementation of policy, mechanisms are needed to minimize sink reversals and impacts of unplanned events that could result in loss of the stored carbon and to provide for replacement of any losses. In the case of SOC sequestration activities, there might be either intentional or 'forced' reversals in which the C sequestering practices are temporarily or permanently reversed. Examples of temporary reversals could include tillage needed for controlling weed infestation or failure of establishing a cover crop. Nontemporary or 'permanent' reversion could include plow out of perennial grass set aside and reversion to annual cropping for economic reasons.

Various ways have been proposed to deal with the risk of nonpermanence, including requiring long project periods so that C-sequestering practices are maintained even after net increases in SOC are nil, as the soil reaches a new equilibrium. However, many land managers may be reluctant to commit to a specific management regime for a long period of time, given the uncertainties of markets, weather, pest infestations, changes in land ownership, etc. An alternative gaining acceptance in the voluntary market system is the use of a permanence buffer system, in which a carbon registry that certifies C offsets for sale withholds a certain percentage of C offset credits as a hedge against unanticipated losses of stored carbon – in effect the buffer acts as a kind of insurance policy. This type of system has been pioneered by Verified Carbon System (VCS), which is the largest registry in the

voluntary GHG mitigation market. In the VCS system, the size of the buffer required for an individual mitigation project varies according to different risk factors, so that the buffer withholding is greater for projects deemed as having a greater risk of nonpermanence. With increased project longevity and mitigation of risk factors the percentage of credits withheld in the buffer can decrease over time. In the VCS, there is a pooled permanence buffer encompassing all projects within the registry, so that permanence in issued credits is maintained even if one or more projects fail, resulting in the release of previously stored carbon.

Leakage

Because GHG emissions are a global-scale perturbation in terms of their effect on climate, it is how much is emitted, and not where the emissions occur, that matters. Thus, it is important that actions taken in one location to reduce emissions do not lead to an increase in emissions elsewhere, thereby reducing or negating the intended mitigation activity. This phenomenon is commonly termed 'leakage' and is defined as an unintended or indirect increase in emissions occurring outside of the boundaries of a mitigation project, due to the implementation of the project. Leakage can be the result of a direct displacement of emission-causing activities from a project area to areas that are not subject to the same emission reduction requirements. For example, if cropland is converted into set-aside land for conservation purposes and GHG reductions, this could cause the crop production activities to move to other noncropland areas (e.g., native forest or grassland). Subsequent land clearance and conversion into cropland production could cause equal or greater total GHG emissions than the reductions occurring on the set-aside land. Leakage can also occur if the project mitigation activities cause an increase in other, nontargeted emission sources within the project boundaries. The other main source of leakage is a more indirect displacement of emissions due to effects on commodity production and supply and demand of products, often referred to as market-based leakage. Market-based leakage is very difficult to precisely quantify due to the fact that many different factors (including ones unrelated to mitigation activities) can influence land-use and management choices.

Leakage associated with soil carbon sequestration practices is likely to be negligible for most practices that do not involve land-use change, such as cropland set-asides (e.g., conversion to perennial grass cover). Changes in tillage practices, crop rotations, winter cover crops, etc. are unlikely to have a significant aggregate impact on commodity production and in some cases, for example, reduction in summer fallow, could positively impact commodity production. For instances where mitigation activities involve land-use change, such as set aside cropland or grazing land as conservation reserves, leakage can be minimized if more marginal agricultural lands are targeted.

Glossary

Avalanching The cumulative effect of saltation and surface creep to disintegrate soil aggregates and increase movement of soil grains with increasing field length to produce greater wind erosion impact.
Interrill or sheet erosion Uniform soil particle detachment by the action of rainfall and runoff as a result of raindrop impact and slaking, which remove thin layers of soil from the land surface.
Rill erosion Soil removal in small, generally parallel channels formed by runoff water.
Saltation Discontinuous wind transport of 0.1–0.5-mm soil particles in a bouncing motion, usually within 300 mm of the soil surface, which is exacerbated by the impact of other saltating soil grains.
Surface creep Movement of 0.5–1.0-mm soil particles that are rolled along the soil surface by wind.
Suspension Wind transport of soil particles <0.1 mm after entering wind streams of varying elevations that may exceed thousands of meters for distances spanning continents.
Threshold velocity The minimum wind velocity required to initiate soil movement from an unprotected surface condition.

Introduction

Soil conservation practices are those farming operations and management strategies conducted with the goal to control soil erosion by preventing or limiting soil particle detachment and transport in water or air. Although some aspects of soil conservation practices may relate to water conservation, and although soil and water conservations are strongly linked, the authors concentrate herein on soil conservation. The objective of this article is to describe soil erosion mechanics and relate that to both traditional and innovative management practices for preventing soil erosion driven by either water or wind. Persuasive arguments depicting an apparent global climate change characterized by extreme weather events, including drought, has spawned a growing concern about soil susceptibility to erosion and fears of reliving the historic North American 'Dust Bowl.' These fears may be assuaged by a more complete knowledge of the array of soil management practices routinely implemented in conventional production agriculture for the purpose of conserving soil resources. This routine application of soil conservation practices followed a developing soil conservation ethic or commitment to land stewardship and greater understanding of both climate and appropriate farming practices.

The westward Euro-American settlement of the US is replete with examples of land degradation and soil erosion. Dabney *et al.* (2012) described water-driven soil erosion problems extending from the US southeastern coastal plain that began with clearing land of virgin timber for agriculture during the 1830s and, for an example, resulted in what was later described in 1910 as the badlands of Mississippi. The native range of the North American bison that includes the southern Great Plains, previously labeled the 'Great American Desert' by explorer Stephen Long in 1820 (Price and Rathjen, 1986), similarly entered agricultural production at the beginning of the 1900s with the encouragement of railroads and land speculators (Egan, 2006; Campbell, 1907). Fueling this migration to the Great Plains was an early claim of anthropogenical climate change that 'rain follows the plow' as professed with certainty by Cyrus Thomas who served as agriculturalist and naturalist for the 1871 Hayden expedition (Bartlett, 1980). The ensuing cultivation implemented the widely adopted farming practices from Campbell's 'A Complete Guide to Scientific Agriculture as Adapted to the Semiarid Regions' (1907) that promoted frequent residue-burying tillage using implements intended for maximum pulverizing of soil. That soil condition was intended to increase rain infiltration plus provide an evaporation-limiting dust mulch and an 'ideal seedbed.' However, some 16 million hectares of potentially erodible soil were exposed and eventually became the Dust Bowl of the 1930s.

The 1909 Bureau of Soils Bulletin 55 provided an impressively extensive survey of the US soil resource prefaced by recent investigations containing the notable claim that the soil was an 'indestructible, immutable asset' (Whitney, 1909). Nevertheless, the Great Plains' agriculture dependency on overgrazing and 'excessive plowing' to produce a dust mulch contributed significantly to wind-driven soil erosion as identified in a 1936 report to President Roosevelt by the drought area committee of Cooke *et al.* (1936). Soil conservation began with the commitment to protect an ecology from agricultural production using largely untested technology that failed to conform the natural requirements of the land. The evolving land degradation could only be understood by determining whether the causes were natural or consequences of unwise use (Tanner, 2012). Hugh H. Bennett, director of the newly established Soil Erosion Service in 1933, indicted Americans as "the greatest destroyers of the land" (Egan, 2006) as illustrated by dust storms resulting from ignorance of and need for improved farming practices. Soil conservation ultimately requires efforts to 'adjust men and machines to land' to reverse what Aldo Leopold referred to as land pathology (Tanner, 2012). The expanding commitment to land stewardship reflected Aldo

Leopold's land ethic that exemplifies a shift from conquering the land-community to becoming a citizen.

Soil Erosion Service director Hugh H. Bennett contributed both the insight and leadership necessary to developing, distributing, and implementing soil conservation practices to control catastrophic soil erosion. To develop soil conservation practices for implementing his insight, Bennett recruited Howard Finnell from the Oklahoma Panhandle in 1934 to conduct a research and demonstration program at Dalhart, TX, USA that featured techniques for increased precipitation capture by minimizing runoff with terraces and contour farming (Duncan and Burns, 2012). Conservation practices of retaining crop residue cover on the soil surface and listing deeper furrows to produce soil clods too large to erode and provide ridges to capture eroding sand were also investigated. Bennett's leadership as a practical tactician was consummately demonstrated during the week following 'Black Sunday,' 14 April 1935, when he delayed his testimony before a US Senate hearing to coincide with the arriving catastrophic dust storm that he heralded by stating "This, gentlemen, is what I'm talking about" (Egan, 2006). This convincing tactic dramatically illustrated the necessity of soil conservation contained within the pending Soil Conservation Act, Public Law 46, which passed without a dissenting vote (Cook, 2003).

Soil conservation during the Dust Bowl faced skeptics that questioned success when the simplest solution of increased rain was unattainable. Bennett observed that "One man cannot stop the soil from blowing, but one man can start it" (Egan, 2006), which suggests guidance on soil conservation practices avoided management mistakes of exposing bare soil to wind or water. Conservation practices sought farming methods that were compatible with the land or reversed the effects of incompatible management for more extreme erosion cases. Practical knowledge of soil destabilization, entrainment, transport, and deposition could lead to attainable solutions for conserving soil.

Soil Erosion Mechanics

Understanding the factors and processes governing soil erosion is important to implementing control practices for managing accelerated erosion. Soil erosion mechanics involve fluid (water/wind) detachment or entrainment followed by transport of soil particles and subsequent deposition as soil sediment. Although erosion processes are important contributors to soil formation, erosion becomes problematic when it is accelerated.

The integrated fluid pressures exerted on soil grains that overcome the soil shear resistance during entrainment were described as three types in a review article by Chepil and Woodruff (1963). Fluid pressure exerted directly against the soil grain is called the impact or velocity pressure and varies with the fluid velocity and density that is applied to the cross sectional area of the soil grain normal to the direction of the flow. The second complementary force is the tractive pressure applied on the lee side of the grain depending additionally on fluid viscosity, and sums with the impact pressure to provide the total drag force applied to the soil grain. The third pressure is the one that exerts an upward tractive force transverse to the fluid direction as a result of the Bernoulli Effect that relates lift to the fluid velocity traveling over the soil grain. These forces have been described in relation to fluid with simple uniform velocities; however, nonuniform fluid velocity facilitates soil movement through turbulent flow that can maximize particle lift and drag impulses.

Soil movement by wind begins when the minimum drag and lift forces exceed the threshold required to move soil grains. Movement can increase with increasing fluid velocity to the maximal threshold velocity that is capable of dislodging all erodible soil fractions. The threshold friction velocity varies as a function of square root of both particle diameter and the ratio of the particle and fluid density. For wind, these drag and lift forces combine to cause soil particles, approximately 0.1–0.5-mm diameter size, to bounce along the surface, striking other soil particles in a process known as 'Saltation' (**Figure 1**). Soil particles in saltation repeatedly impact the soil surface and may briefly dislodge larger soil particles, approximately 0.5 to <0.84-mm diameter, to roll along the surface as 'Surface creep' until stopped by larger soil particles and aggregates or areas protected from wind, including furrows, fence rows, and ditches. Saltating soil may also strike particles <0.1 mm, ejecting them into the windstream for sustained transport in

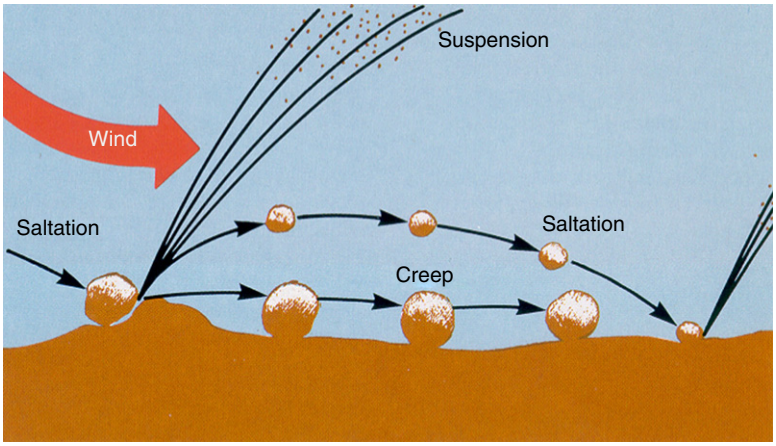

Figure 1 Diagram showing types of wind-driven soil particle movement including saltation that can promote surface creep, suspension, or continued saltation. Graphic courtesy of USDA-ARS Engineering and Wind Erosion Research Unit.

'Suspension.' Suspension also results from erosion of loose particles and the fracture of larger particles during the saltation process. Of these soil movement types, saltation is responsible for between 50% and 75% of the eroding soil mass with 3–40% carried in suspension and from 5% to 25% moved as surface creep. The cumulative effect of saltation on soil aggregates and grains increases with field length for greater erosion or the 'Avalanching Effect.' Because soil movement in saltation promotes both surface creep of coarse grains and suspension of dust, the most effective conservation practices are provided by limiting factors and conditions resulting in saltation.

Soil movement by water often starts when a raindrop impacts the soil surface and initiates splash erosion, i.e., raindrops break aggregates into finer soil particles, displacing those particles and aggregates to create depressions in the soil surface. The splashed soil particles clog the pores during rain infiltration to form less conductive surface seals that increasingly decrease rainwater infiltration. Water that does not infiltrate into the soil flows over the field surface and can entrain sediment. The declining capacity of the soil to absorb rainwater increases the volume of runoff available for interill water erosion. Water erosion depends on rainfall intensity, soil erodibility, and field slope among other factors.

Splashed soil particles are prone to rapid removal by interrill and rill erosion; thus interconnecting these erosion processes. Interrill erosion, also known as sheet erosion, occurs as uniform surface flow, whereas rill erosion occurs when runoff concentrates in small and shallow depressions. Interrill and rill erosions are the most dominant forms of water erosion; however, increased runoff transport capacity coupled with high runoff volume leads to the more catastrophic gully erosion. Sloping fields with little or no vegetative cover are prone to gully erosion that may be temporarily erased with tillage operations, but growing ephemeral gullies often require mechanical structures or changes in land cover and use to reduce erosion and prevent permanent gullies. Mechanical structures and agronomical or biological practices may be used to manage and control water erosion. In other words, accelerated soil erosion is an avoidable process.

Soil susceptibility to erosion processes will increase with the prevalence of soil destabilization factors that depress durability and particle cohesiveness. For example, the combined effects of limited precipitation and high air temperatures commonly experienced during drought may decrease the soil organic matter effective in stabilizing aggregates as well as the benefits of water films to improve soil particle cohesion noted for damp soil. Chepil and Woodruff (1963) illustrate this point for silt loam soil erosion rates that increased by over one order of magnitude at 11.6 m s^{-1} wind velocity when soil water content equivalent at −1.5 MPa water potential decreased by 75%. The finer grains of dry soil are more susceptible to wind erosion, a condition that persists after 2 years of drought and is only reversed by more than 2 years with favorable moisture and vegetation growth. Sustained drought can displace microbial communities in favor of those capable of tolerating desiccation or radiation such as *Bacteriodetes* that survive in ecological soil niches normally associated with erodible fine soil grains (Gardner *et al.*, 2012). Displaced communities include the *Proteobacteria* that promote C and N cycling and are associated with less erodible coarse soil particles.

In the absence of residue cover, structural breakdown of soil aggregates becomes problematic due to weathering or frequent tillage. The weathered or excessively tilled soil forms a smooth surface that promotes greater wind velocity and produces fine soil grains that are susceptible to wind or water erosion. Saltation, surface creep, and suspension often sort soil grains prone to movement on the leeward side of small aggregates. This soil movement also provides for abrasion of any aggregates or stable rain-formed crusts, which are also sorted and further supplement the supply of erodible soil grains. Soil deposition by sedimentation or trapping in deep cross-ridges and large aggregates prevents or stops continued soil movement and the erosion process. Reduced tillage and improved cropping practices can increase residue retention and preserve soil aggregation.

Integrating Wind Erosion Factors

Early efforts to estimate wind-driven soil erosion resulted in the 'Wind Erosion Equation' (WEQ) developed by W. S. Chepil and published by Woodruff and Siddoway (1965). The WEQ functional form:

$$E = f(I, C, K, L, V)$$

estimates the mean annual soil loss by wind (E) from agricultural fields depending on soil erodibility (I) as adjusted for the effects of ridge roughness (K), length (L) along the prevailing wind erosion direction, climatic factor (C), and vegetative factor (V). Empirically combining these factors to estimate soil erosion permitted potential interaction of factor-contributions for controlling erosion and possible conservation practices.

The soil erodibility I-factor is based on a wide, smooth, and unsheltered bare field with erosion loss being controlled by various fractions of erodible aggregates <0.84 mm. Increasing the percentage of erodible soil particles or aggregates also increases I. The effects of wind velocity and soil moisture on erosion are, generally, independent climate C-factors, but permit adjustments for adapting calculations to multiple regions. Soil roughness, K-factor, combined with field L-factor related to orientation and length, represent less adaptable management inputs available to limit exposure of erodible soil or trap saltating soil. The vegetative V-factor characterizes both quantity and type of crop residue that can reduce wind velocity and, consequently, erosion. The empirical WEQ was revised to the RWEQ (Fryrear *et al.*, 2000), which more completely represented the factors governing wind erosion for improved annual soil loss estimates and fostered the development of a more comprehensive process-based wind erosion prediction system (WEPS); Hagen *et al.*, 1999).

On a daily time step, WEPS integrates climate, soil properties, management practices, and crop residue input data with governing transport relationships as summarized by Chepil and Woodruff (1963) to calculate soil erosion. Thus, when the threshold friction velocity is exceeded, movement of soil including PM-10 is estimated from interacting saltation, surface creep, and suspension processes for a specified region. Soil

surface roughness conditions are updated to reflect dynamic detachment and deposition processes that modify aggregation and residue status and the related susceptibility of soil to erosion. As reported by Hagen (2004), these more accurate estimates of soil erosion in response to the combined effects of soil crust and residue cover, aggregate size and stability, and ridge height and random roughness can improve the coordinated application of conservation practices.

Integrating Water Erosion Factors

Empirical soil erosion estimation methods have resulted from research characterizing water-driven erosion as moderated by potential conservation practices. Various factors affecting soil erosion, including soil slope and length or supporting control practices like contour rows, strip cropping, and terrace systems, were recognized as independent factors influencing soil erosion by their inclusion in regional soil-loss equations beginning in 1940 (Wischmeier and Smith, 1978). Eventually, a national committee's effort to predict soil erosion proposed a universal soil loss equation (USLE) that retained field length and slope (LS), crop cover and management (C), and support practices (P). This new relationship estimated annual soil erosion amounts (A) as mass per unit area independently of regional soil and climate differences with the addition of terms describing the combined rainfall and runoff erosivity (R) and soil erodibility (K) or susceptibility to erosion. The resulting soil loss equation is:

$$A = RKLSCP$$

The rainfall and runoff or R factor is a spatial erosion index (energy·rain-depth/area·hr·year) that increases from <20 in western USA to 550 along the southeastern US Gulf coast and reflects both the amount of rain and its energy, which increases with rain intensity and increasing drop size and terminal velocity. Soil erodibility indexes soil loss potential in relation to texture and percent organic matter as a first approximation for K (mass·area·h/energy·rain-depth) that ranges from <0.1 to 0.7. The K value is further refined by considering soil structure and profile permeability to characterize potential infiltration and internal drainage, which can further influence runoff and soil movement. The soil LS topographical factor compares slope angle and field length contributions to runoff energy from fields in contrast to a standard uniform 9% slope and approximately 22-m length. Varying field slope from 9% affects runoff energy that is cumulative with length resulting in dimensionless LS values that vary from <0.1 to approximately 12.9. The crop cover and management C factor is a dimensionless time-weighted index characterizing soil cover due to residue management and crop canopy condition as a percentage compared with clean till (bare) fallow. Lastly, the supporting dimensionless conservation practice P-factor indexes potential soil loss of various conservation practices such as contour rows, strip cropping, and terrace systems to up-and-down slope straight-row farming. The P-factor revisits, somewhat, field length and slope effects on soil erosion as managed using agricultural practices.

Efforts to estimate soil erosion have steadily evolved from empirical methods to the process-based mechanistic computer simulation approach of the water erosion prediction project (WEPP) as summarized by Nearing *et al.* (1989). The primary erosion processes of detachment, transport, and deposition as modified by residue cover or the cover of a growing crop canopy were based on the quantified fundamental erosion agents of rain infiltration, surface runoff, plant growth, residue decomposition, and soil management. The advantage of a mechanistic model is its design to accommodate spatial variability of topography, surface roughness, and soil properties in addition to variable hydrology and land-use application.

The WEPP process-based estimate of soil loss employs a continuity equation that relates sediment load in the runoff to the distance downslope as a function of the interrill and rill erosion rates calculated on a daily time step. Interrill erosion is the process of sediment delivery to more concentrated flow in rills, but rill erosion depends on the potential detachment capacity as limited by the sediment transport capacity of runoff in the rill. Rill and interill runoff must produce a hydraulic flow shear stress sufficient to exceed the minimum shear stress required to detach soil, depending on the soil erodibility. In contrast to soil erosion, deposition is calculated when sediment load exceeds the sediment transport capacity. The hydrological factors driving these processes are rainfall intensity and runoff rate and duration, which govern flow volume in the rill and combine with other factors such as slope gradient and friction in determining flow shear stress.

Field interill erosion model estimates in WEPP combine the base soil erodibility and erosion agents with spatial varying factors such as rill frequency and width. Modeled temporal variations in soil erodibility replicate decomposing residue cover, soil consolidation for reduced roughness, and crop factors. Temporally dynamic crop canopy height and cover that varies due to plant growth also directly modifies the soil-water balance and related rain infiltration. The growing crop further complicates erosion estimates by interactions with temporal varying seasonal rain and the factors for adjusted soil erodibility. The resulting mechanistic soil erosion calculations permit useful comparisons of conservation practices by incorporating climatic details and interacting seasonal crop growth.

Conservation Practices – Wind Erosion

Conservation practices implemented to control wind erosion act directly to: (1) increase the size of exposed soil aggregates in excess of the wind entrainment capacity, (2) reduce wind velocity sufficiently to prevent sediment entrainment, and (3) provide a barrier between the soil and wind. An indirect wind erosion control can act by reducing evaporation, thereby leading to increased soil water content that improves soil cohesiveness. Conservation practices may exhibit a common mode of action like reducing wind velocity to similarly control erosion, but at different scales ranging from crop-row spacing to field width. Conservation practices often provide two or more modes of action such as residue mulches that reduce evaporation of soil water to promote soil particle cohesiveness, increase overall crop biomass productivity, and provide a protective barrier for greater erosion control. Many conservation practices represent mature technologies, including

management of standing residues from previous crops to decrease wind velocity and control erosion (Woodruff *et al.*, 1972), but innovative approaches to residue management such as the application of new weed control chemistries for converting cover crops into dry mulches modernize that technology.

Emergency Tillage

Tillage alternatives are necessitated by the absence of adequate crop residue to form a barrier that prevents soil erosion. Drought often prevents crop growth sufficient to form adequate residue cover. Emergency tillage roughens the soil surface to conserve soil by producing large clods or aggregates. Examples include cultivation by primary tillage practices and specific purpose implements like the 'sand fighter' (**Figure 2**). The resulting aggregates are larger than can be transported by the wind and temporarily stabilize the exposed soil until saltating grains cause clods to disintegrate. Tillage can be used to stop an ongoing erosion process from an involved field and is applied beginning along the upwind edge of the eroding field using a chisel or lister plow to expose coarse subsoil aggregates. Chisel plows are often preferred because they preserve available crop residue. In contrast, disk plows or harrows are generally not suitable for emergency tillage because the soil is pulverized, which may contribute to the saltating grains in the erosion process.

This tillage practice should, ideally, disrupt the soil surface in tilled strips that are perpendicular to the direction of the wind. The tilled soil strips may be roughened or ridged to reduce wind velocity at the soil surface, but should provide a surface with nonerodible soil aggregates >0.84 mm and, preferably, larger clods capable of trapping the saltating soil particles. Tillage strip frequency may be governed by operational requirements of the machinery and, occasionally, will require additional emergency tillage between strips to control movement of saltating grains. The tilled strip spacing will vary with soil texture from approximately 30 m for sandy loam soils to approximately 120 m for clay loams. Nevertheless, the on-going saltation and surface-creep erosion processes dictate that emergency tillage is a temporary conservation measure of last resort, remaining effective only until clods disintegrate.

Crosswind Ridges, Terraces, and Contours

Crosswind ridges consist of tall listed seed beds that are formed over the entire field or as trap strips with an orientation perpendicular to a required prevailing wind direction (**Figure 3**). Although not an emergency conservation practice, crosswind ridges also exploit the larger soil aggregates present after lister tillage and the much increased roughness that reduces near-surface wind velocity to limit soil erosion. In addition to the decreased wind velocity that reduces the transport capacity of the wind, much of the wind erosion control results from between-bed interception or surface clod trapping of soil grains moving in saltation and surface creep. Crosswind ridges realize greater success for soils capable of producing large stable aggregates compared with sandy soils.

The formation of an earthen embankment along a common elevation contour produces an elevated terrace structure that can directly reduce wind erosion by potential reduction in wind velocity and interception of saltating soil grains. Permanent tall grass vegetation or annual forage and cereal cropping as a strip on the terrace can augment trapping of soil grains and further reduce wind velocity. Indirect wind erosion control benefits of terraces and the related contour tillage and cropping practices expand overall crop grain and residue productivity by controlling runoff for increased water storage in the soil (Duncan and Burns, 2012).

Wind Breaks – Shelterbelts

One of the more aesthetically pleasing and permanent conservation practices for controlling wind erosion includes agroforestry shelterbelts or windbreaks (**Figure 4**). Windbreaks may contain single or multiple rows of evergreen and/or deciduous trees supplemented with shrubs or grasses that are planted in linear strips perpendicular to the prevailing wind (Brandle *et al.*, 2004). A windbreak serves as a barrier with the purpose of deflecting air flow and reducing the leeward wind

velocity, which varies with windbreak height, spacing frequency, and porosity. Windbreaks control wind erosion by reducing surface wind velocity below the minimum threshold for soil movement and remain effective during drought when other conservation practices fail. These barriers can also reduce wind velocity sufficiently to decrease its soil-carrying capacity, resulting in soil deposition and possible dune formation.

The success of shelterbelts to effectively reduce wind velocity, albeit limited depending on porosity to distances from the belt of 5–12 times the tree height, combines with improved wildlife habitat and livestock protection to encourage the application of this conservation practice. The wind erosion control benefit is not, however, immediately available with this conservation practice and, depending on the tree growth rate, will be delayed by several years. Actively growing trees also compete for space and water resources with nearby cropped land, resulting in tree root exploration that can extend some 2.5 times the tree height (Chepil, 1965). Alternatively, Brandle *et al.* (2004) observed windbreak effects to reduce air flow also resulted in a beneficial distribution of snow and a general reduction in evaporation that benefited nearby crops. These contrasting crop responses to windbreaks may reflect spatial differences in potential crop water stress indicated by the ratio of precipitation to the potential evapotranspiration that, in the continental US, increases when proceeding from south to north or west to east (Follett *et al.*, 2012). Similarly, the historical 1935–42 shelterbelt establishment in the eastern Great Plains and the ongoing shelterbelt renovation in the northern Great Plains appear in less arid regions. The availability of irrigation makes this conservation practice viable in a difficult environment.

Strip Cropping

Crops may be cultured in strips perpendicular to the prevailing wind where field orientation is not restricted as a means to reduce the near surface wind velocity (Chepil, 1965; Woodruff *et al.*, 1972). Cross-wind strips typically subdivide fields with alternately planted erosion-controlling crops and erosion-susceptible crops or fields. These strips effectively reduce the field width and limit downwind soil avalanching. The design distances between strips vary with soil erodibility, ranging from approximately 30 m for a sandy loam soil to 100 m for clay loam, but are further complicated by the required compatibility with farm machinery. Nevertheless, cross-wind strip cropping typically accommodates most crop rotations with only limited impact on net production.

Figure 5 Cimarron County, Oklahoma, site of the Arthur Coble farmstead, in April 1936 (inset) and present day, revegetated with various grass species after enrolling in the Conservation Reserve Program (CRP) to prevent wind erosion. Inset photograph by Arthur Rothstein (Library of Congress), present day photograph courtesy of Cimarron County NRCS.

The strip cropping conservation practice is broadly accommodating of variable width crop strips and interstrip widths, depending on crop tolerance to eroding soil or potential to trap saltating soil grains. This adaptation of strip cropping for trapping saltation does impose a width requirement of 5–8 m depending on the height limitations of the strip crop. Relatively narrow two-row strips can be cropped using sudangrass or grain and forage sorghum to reduce near-surface wind velocity and control soil grain movement as a herbaceous wind barrier. Taller perennial grasses can provide similar erosion control in semiarid regions where crop establishment and growth are unpredictable.

Rangeland and Permanent Cover

Erosion is possible when soil grains susceptible to movement by saltation are exposed through some destabilization process, including excessive tillage or grazing (Chepil and Woodruff, 1963). Effective soil conservation practices thus include avoiding soil disturbance for crop production on marginal lands. The economics driving agricultural production that firmly entrench areas for permanent range management may, however, alternately encourage or discourage sustainable stocking rates as a result of market volatility. Some marginal lands have been designated as highly erodible and were to some extent returned to permanent cover management under the US federal government's 'Conservation Reserve Program' included in the 1985 Farm Bill. Various tall-grass species are cultured on marginal lands with no grazing as a means to remediate the soil of an eroded site (**Figure 5**).

The protective value of a residue cover is functionally related to residue mass, stem density, and orientation, but is expressed as an equivalent of a small-grain crop reference that is 25-cm long flattened wheat residue cultured in rows 25 cm apart and parallel to the wind direction (USDA-NRCS, 2002). Undisturbed crop covers are more effective at preventing soil movement when residues are standing, perpendicular to the wind, and have numerous stems. For example, flat randomly oriented wheat straw provides the same protection as 1.6 times the reference straw mass. Standing wheat residue oriented perpendicular to the wind is 3.5 times more effective than the reference for protecting soil from wind erosion. An example of poor protective value of crops with large stem size and reduced number is reflected by the 0.225 small grain-equivalent reference mass for standing sunflowers, meaning that 1.1 Mg ha^{-1} of sunflower residue provides soil protection equal to only 0.25 Mg ha^{-1} of flat wheat residue.

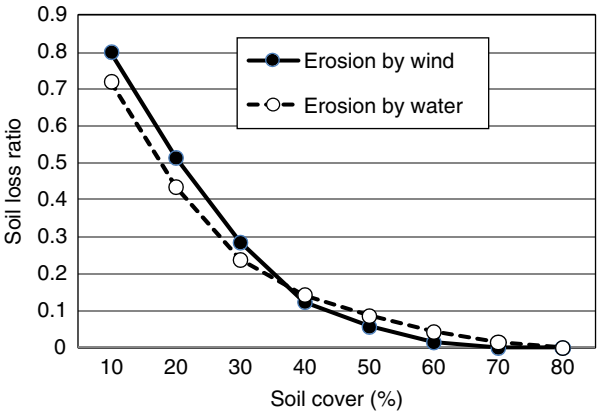

Figure 6 Relationship between soil loss ratio (soil loss with cover divided by loss from bare soil) and percentage of surface cover by residue for erosion by wind and water. Reproduced from Papendick, R.I., Parr, J.F., Meyer, R.E., 1990. Managing crop residues to optimize crop/livestock production systems for dryland agriculture. Advances in Soil Science 13, 253–272.

Residue Management

Residue management generally is the preferred control method for wind erosion for most crops and climates (Fryrear and Skidmore, 1985). It comprises various tillage practices that maintain residue from a previously harvested crop as a surface cover to prevent soil erosion. Protection is by providing a barrier that reduces wind velocity below the threshold for erosion. Ideally, standing crop residues are retained to reduce the velocities or deflect near-surface winds so that insufficient force is available to entrain and transport soil particles. Flat crop residue, although less effective for reducing wind velocity, still provides a critical barrier that shields soil aggregates from abrasion by saltating soil grains and disintegration to an erodible size. Residue management also maintains mulches, either standing or flat, to intercept soil grains by trapping their movement to reduce saltation, surface creep, or suspended soil movement for wind erosion control. Harvesting residue to supply bioenergy is, however, one management consideration that varies with the crop and resulted in unsustainable wind erosion (modeled with WEQ) after removing 10–30% of dryland corn stover and 80% wheat straw under no-till (Miner *et al.*, 2013).

Although control of soil erosion by wind or water varies with residue cover as shown in **Figure 6**, that cover must exceed approximately 30% to minimize soil loss (Papendick *et al.*, 1990) and meet conservation compliance. Conservation tillage includes strip-till, stubble-mulch till, and no-till practices that eliminate the more disruptive and potentially pulverizing inversion tillage that incorporates crop residue, providing less than the 30% minimum soil cover. In contrast with no-till retention of all residue at the soil surface, inversion-type primary tillage implements such as moldboard or disk plows eliminate, on average, 95% of the residue cover compared with crop residue incorporation of 10–40% for stubble-mulch tillage sweep plows and from 20% to 40% with chisel tillage (Unger *et al.*, 2012). Leaving residue from the previous crop on the soil surface has the added benefit of improved soil water storage, regardless of runoff-controlling contours, by increasing rain infiltration and decreasing evaporation. Greater soil water contributes to soil cohesiveness and reduces the fraction of erodible particles. But, improving soil water storage with residue management increases crop productivity for greater potential soil cover and stabilizing organic matter.

Cover Crops

The cover crops conservation practice describes the culturing of a crop primarily for the purpose of controlling erosion. Cover crops are necessary for erosion control when principal crops produce insufficient or unsuitable residue for more conventional residue management-based erosion control. For example, a cotton monoculture does not provide adequate residue to provide >30% ground cover to prevent soil loss or add organic matter to maintain soil stability. Yet, favorable cotton production economics encourages this monoculture in semiarid regions despite the expectation of intense spring winds eroding susceptible bare-tilled and dry soils. With irrigation, one solution has been to plant cereal crops, including winter wheat, rye, or oats after cotton harvest exclusively for temporary prevention of wind erosion during the idle period before planting cotton again (Keeling *et al.*, 1989). In addition to wind erosion control, a herbicide-killed wheat cover crop provided residue for increased rain infiltration and reduced evaporation that improved subsequent crop growth.

Dryland cover crop production in the semiarid western Great Plains competes for limited precipitation and frequently results in inconsistent crop establishment and production results. For this reason, Baumhardt and Lascano (1999) concluded that establishing dryland cotton after a wheat cover crop was problematic and contributed to production risk. Where precipitation is adequate, cover crops like field peas can supplement the wind erosion control benefit from residue cover with the addition of fixing nitrogen and preventing weed establishment or competition for water.

Soil Amendments

Using soil amendments as a conservation practice for wind erosion control is almost exclusively applied to small vulnerable

locations, 'blowouts' or knolls, to prevent saltation erosion from spreading to other fields (Woodruff *et al.*, 1972). Natural soil amendments include crop residue in the form of straw or hay and crop-processing byproducts such as corncobs or cotton gin trash that are typically anchored by shallow tillage operations with a rotary hoe or mulch treader. The applied plant biomass functions primarily as a mulch barrier to prevent abrasion and to trap saltating soil grains, but can act to reduce soil surface wind velocity. Similar to plant materials, livestock manure functions to intercept and trap saltating soil grains and depress wind velocity at the soil surface; however, manure nutrients must be managed for the benefit of crops.

Synthetic amendments functioning as adhesives for binding soil grains are applied to temporarily stabilize eroding soil affecting high-value crops (Armbrust and Lyles, 1975). These materials include resins, asphalt, latex, polymers, and polyvinyls, but may not be compatible or effective with all crops or soils. Treatment efficacy preventing soil erosion can be lost after any postapplication rain event, abrasion by saltating soil grains from adjacent fields, or use of cultivation. More recent investigation of wind erosion control using various formulations and application rates of polyacrylamide (PAM) indicated this amendment was ineffective (Armbrust, 1999).

Conservation Practices – Water Erosion

Mechanical Structures

Various mechanical or engineering structures can be used for control of water erosion. Among these are terraces, drop structures, spillways, culverts, gabions, ripraps, and ditches. Mechanical erosion control practices reduce runoff velocity, store runoff water, and convey runoff at nonerosive velocities. There are also mechanical structures for harvesting rainwater that is stored for immediate or later use. These structures control water erosion by reducing rainwater available for runoff. Some of the common water-harvesting structures are farm ponds, storage tanks (underground or aboveground), and check dams. Mechanical structures are important companion practices to biological or agronomical practices such as conservation tillage (i.e., no-till and reduced till), residue mulching, cover crops, and conservation buffers. Mechanical practices are especially needed to reduce concentrated flow and gullying when biological practices alone can be insufficient.

Terracing is the most common mechanical practice to reduce runoff velocity and safely divert runoff to an outlet. Terraces reduce the slope length by splitting large fields into smaller strips and can be more effective than biological practices for reducing water erosion in sloping soils. In soils with steep slopes, residue mulching and cover crops can fail to control concentrated runoff flow and gully formation but are effective at controlling interrill and rill erosion. Terraces are practices similar in their function to other cultural practices such as contour farming and strip cropping.

Use of silt fences and surface mats are also important methods to control water erosion. Silt fences and surface mats are often used as temporary measures in disturbed lands or construction sites until permanent structures and conservation practices are established. Silt fences are vertical synthetic fabric barriers that reduce runoff velocity, filter sediment, and reduce off-site transport of sediment. Silt fences can reduce approximately 80% of total suspended sediment in runoff (Barrett *et al.*, 1998). Surface mats can buffer raindrop impacts, hold the soil in place, reduce surface sealing and crusting, enhance vegetation establishment, filter sediment in runoff, and stabilize disturbed soils. Silt fences and surface mats may be made of geotextiles or appropriate plant by-products such as straw, straw bales, coir, paper waste with binders, and wood chips, for example. Mechanical structures and practices should be used in combination with agronomical or biological practices.

Agronomical or Biological Practices

Agronomical practices such as conservation tillage, residue mulching, and cover cropping are soil conservation practices, whereas mechanical structures are typically water-control practices. Biological practices such as residue mulching and cover crops keep the soil in place. In contrast, mechanical engineering structures are effective practices for intercepting and redirecting runoff, promoting sedimentation, and reducing off-site transport of sediment. Biological practices maintain a permanent vegetative or surface cover to reduce erosion and are preferable over mechanical practices, especially in soils with gentle or moderate slopes. Well-established and site-specific agronomical practices can effectively reduce runoff, increase water infiltration, and reduce soil loss.

Conservation tillage has been defined as any tillage system that leaves at least 30% of residue on the soil surface. It includes a number of tillage systems such as no-till, minimum tillage, mulch tillage, strip tillage, vertical tillage, and ridge tillage. In the US, the Dust Bowl in the 1930s heightened the interest in conservation tillage practices. Development of preemergent herbicides in the 1960s further enhanced the use of conservation tillage practices such as no-till. The potential of conservation tillage to reduce water erosion is widely recognized. Indeed, conservation tillage was conceived to reduce soil erosion from croplands. Its increased use has reduced the need for mechanical structures (i.e., terraces), particularly in moderately sloping soils.

No-till is an effective conservation tillage system to reduce soil erosion that succeeds by maintaining a near constant residue mulch cover. No-till soils with complete residue cover may completely eliminate soil loss. As a result, no-till performance depends on the amount of residue left on the soil surface after harvest. If residues are grazed, baled, or burned, or crops are harvested for silage or to produce ethanol, surface cover decreases and can rapidly diminish the ability of no-till soils to reduce soil erosion. Similar to plowed soils, no-till soils may create surface seals and erode when residue cover is insufficient. In semiarid regions, limited residue production under no-till may limit the potential of no-till to effectively control water erosion. Surface residue mulch is more effective at reducing splash, interrill, and rill erosion than at controlling concentrated runoff or gully erosion.

Crop residues intercept the erosive energy of raindrop impacts and reduce near-surface aggregate detachment, aggregate slaking, and surface sealing (**Figure 7**). When raindrops impact bare soils, surface seals develop and rainwater infiltration

Figure 7 No-till irrigated corn near Colby, KS, with corn stover retained (top) or removed (bottom). In the absence of residue to intercept water drops, a soil crust formed with the potential to restrict seedling emergence.

Figure 8 No-till sorghum fields near Hays, KS, retain declining residue cover with increasing time since harvest, showing that no-till soils can become progressively more erodible.

rapidly decreases; but when raindrops impact residue mulch, rain loses its kinetic or erosive energy, water moves through the residues, and water infiltration is less affected by surface sealing. Crop residues also reduce the erosivity of incoming runoff by intercepting runoff and reducing its velocity. By intercepting runoff, residues increase the opportunity time for infiltration and filter sediments in runoff. Residue cover increases time to runoff (the time between the beginning of precipitation and beginning of runoff) because of increased water infiltration, which concomitantly reduces runoff amount and reduces the number of precipitation events that result in runoff.

Baling or removal of crop residue exposes soil surface to raindrop impacts and reduces surface roughness to intercept runoff. As the amount of residue removal increases, water infiltration decreases and water erosion increases. Percentage of soil covered with residues is a critical factor that affects water infiltration and the amount of water that runs off the field (Figure 8). Between 60% and 80% of rainwater is lost as runoff from bare soils compared with residue mulched soils. Leaving a soil bare is a recipe for increased soil loss. No-till management combined with residue mulching and cover crops is the most effective strategy to prevent and control water erosion.

No-till with residue mulch provides a dual function. It reduces both erosivity of raindrops and soil erodibility due to residue cover and organic matter input. This combined action of no-till decreases soil-erosion risks compared with other tillage practices that disturb soil and bury crop residues. No-till reduces soil erodibility by improving near-surface soil structural properties. For example, soil aggregates under no-till are more stable than under conventional till. Residue-derived soil organic C combined with microbial activity under no-till promotes soil aggregation. Soil organic matter has organic binding agents that enmesh and bind soil particles into stable aggregates. Soil aggregate stability is strongly and positively correlated with management-induced increase in soil organic carbon.

Improved soil aggregation results in greater macroporosity and water infiltration and lower runoff rates. In some environments, soil aggregates and macropores under no-till remain practically undisturbed. No-till soils may also have abundant earthworms, which increase water infiltration and reduce the amount of water available for runoff. Earthworm channels and biopores can increase water flow by as much as 100 times compared with soils without biopores (Edwards *et al.*, 1990). Soil macropores open to the atmosphere are protected by the residue cover. In semiarid environments, however, soil water content may be too small to support abundant soil fauna and microbiota, reducing the beneficial macropore formation and soil aggregation typically found in more humid environments. Some semiarid soils consolidate under no-till practice, forming relatively dense and impermeable surface layers. In such environments, judicious use of limited tillage systems may improve infiltration while leaving surface plant residues relatively undisturbed.

No-tilled soils also have greater critical shear stress than soils under conventional till. This means, no-till soils are harder to shear than plowed or loose soils. Thus, under similar runoff transport capacity and hydraulic-shear stress, plowed soils have greater risks of developing rills and gullies. No-tilled soils also have lower erodibility than conventional tilled soils

because of the higher critical shear stress. Soil erodibility and critical shear stress parameters are important to understanding the soil's resistance to concentrated flow erosion.

No-till can reduce soil loss by as much as 90% compared with conventional till. No-till is more effective at reducing sediment loss than runoff. It may not always reduce runoff compared with conventional till, but its effectiveness for reducing soil loss is far superior. Soil surface consolidation may increase runoff in no-till compared with conventional till in some soils. This can be particularly true in clayey and flat soils (Rhoton *et al.*, 2002). It is important to note, however, that runoff leaving no-till soils is typically cleaner and has less sediment than from conventionally tilled soils. Residue mulch filters sediment particles in suspension.

Some of the site-specific challenges with no-till management include soil compaction, stratification of soil organic carbon and nutrients near the soil surface, and others, but its effectiveness for controlling water erosion is unparalleled among all tillage systems. No-till benefits for reducing soil erodibility are more clearly observed in the long term as soil structural properties (i.e., macroporosity, aggregate stability, and infiltration) and organic matter content increases. Depending on the extent of soil disturbance and amount of residue left on the soil surface, reduced tillage, stubble-mulch tillage, strip tillage, and ridge tillage also reduce soil loss more than conventional till but less than no-till management.

Conservation Buffers

Conservation buffers include vegetative filter strips, grass barriers, grass waterways, and riparian buffers. These buffers are designed to intercept runoff flow and reduce runoff velocity and transport of sediment and sediment-bound nutrients, thereby reducing risks of nonpoint source water pollution. Buffers spread the incoming runoff, filter sediment, and promote sedimentation. Debris or plant residues mixed with buffers help to trap sediments and nutrients. Buffers can also stabilize soil and promote water infiltration through their roots. Conservation buffers can trap $>70\%$ of sediments and $>50\%$ of nutrients, depending on the type of buffer, plant species, management, rainfall intensity, and soil slope. These practices can differ in design, vegetative species, and management.

Vegetative filter strips: These are 5–15-m wide strips of vegetation established at the bottom perimeter of croplands. Filter strips are often planted to cool-season grasses including tall fescue, Kentucky bluegrass, orchard grass, smooth bromegrass, and others. Filter strips are a common conservation practice to reduce off-site sediment and nutrient transport in croplands. Filter strips of approximately 10-m wide can reduce sediment loss by 90% in moderately sloping soils.

Grass hedges: These hedges are 0.75–1.2 m-wide strips of stiff, perennial, and tall grass established at short intervals (<15 m) within croplands perpendicular to the main field slope. Grass hedges are grown parallel to row crops on the contour. Grass hedges are commonly planted to warm-season grass species such as switchgrass (Kemper *et al.*, 1992). Other perennial warm-season grasses include eastern gamagrass, indiangrass and big bluestem. In tropical environments with hilly terrains, vetiver grass (elephant grass), a perennial and stiff-stemmed species, is used as hedges to control erosion. Vetiver grass can grow on steep terrains (30% and 60% slope) and can be used like bench terraces. Various Andropogon species are also used for erosion control, being grown on terraces in, for example, Burkina Faso.

Grass hedges differ from vegetative filter strips because they have stiff stems and are often planted to perennial and native warm-season grass species. Grass hedges intercept and pond runoff above hedges, increase infiltration, promote sediment deposition, and form natural terraces upslope of the hedges with time. Grass hedges are well suited to moderately sloping soils to reduce interrill and rill erosion. On steep sloping soils, effectiveness of grass buffers for reducing concentrated flow and gully formation may be limited.

The aboveground biomass of grass hedges intercepts runoff and promotes sediment deposition, whereas the belowground biomass with extensive and deep roots stabilizes the soil, promotes soil aggregation, and improves water-transmission characteristics. Soils within grass hedges often have greater aggregate stability, water infiltration, saturated hydraulic conductivity, macroporosity, organic matter content, and lower bulk density compared with rows without hedges (Rachman *et al.*, 2003).

Riparian buffer strips: These consist of 5–30-m wide strips of mixture of grasses, trees, and shrubs planted between croplands and streams. Riparian buffers have been used more commonly than grass hedges to control water erosion. These buffers not only slow runoff flow and filter sediment but also can improve wildlife habitat and diversity and provide numerous additional ecosystem services. Riparian buffers can reduce runoff and sediment transport by at least 30% (Sheridan *et al.*, 1999). Water infiltration rates under riparian buffers are often higher than under annual row crops. Buffers consisting of sparse trees may not be as effective as those mixed with grasses for reducing incoming runoff and filtering sediment and nutrients.

Grass waterways: Another common conservation practice, grass waterways are natural or constructed channels under perennial grass established along the sides and lower perimeter of fields to convey runoff at nonerosive velocities from terraces, field outlets, and diversion systems on moderately sloping fields ($<5\%$). Dense grass species in grass waterways can filter runoff, reduce sediment and nutrient transport in runoff, and prevent gully formation. The grass waterways can also trap and biodegrade pollutants such as herbicides in runoff. These practices can be combined with drop structures (dam, embankment, and weir) established perpendicular to the main slope at different points within the waterway.

Cover Crops

Cover crops are another effective soil conservation practice to reduce runoff and water erosion. Cover crops are not a new practice, but there is renewed interest in using cover crops to conserve soil and improve soil productivity. Benefits of cover crops for reducing soil erosion are well recognized. Cover crops provide permanent surface cover between growing seasons of main crops. After termination, residues from cover crops continue to protect the soil from erosion. Incorporating cover crops into the soil as green manure reduces their benefits

to soil erosion control as opposed to leaving cover crop mulch on the soil surface. Therefore, cover crops are a potential companion practice to no-till and intensified cropping systems (Figure 9).

These crops also provide many other ecosystem services including improvement in soil properties, soil fertility, biological diversity, and water quality. Cover crops perform a dual function because they protect the soil surface and improve soil properties. Cover crops increase infiltration, create macropores (i.e., earthworm burrows), improve aggregate stability, and increase soil organic matter content and soil microbial biomass. Roots and microbial processes provide labile C to contribute to aggregate formation and stabilization. Improved soil aggregate stability leads to increased water infiltration and reduced soil's susceptibility to erosion.

Surface canopy and residue cover provided by cover crops buffer against the erosive energy of raindrops. It also intercepts upstream runoff and promotes water infiltration. Cover crops also increase the amount of below ground biomass. Cover crop roots under no-till interact with the soil to reduce soil erodibility. Plant roots can strengthen the soil aggregates and anchor the whole soil. Cover crops may also reduce concentrated flow erosion due to the presence of roots even when surface cover is reduced such as during winter. Root density among cover crops differs. Cover crops with fine and extensive roots such as rye and oats can prevent concentrated flow erosion.

Cover crops are becoming a part of intensified cropping systems under conservation tillage in semihumid or humid regions. Cover crops can be grown in winter after summer crops or in summer or fall after winter crops such as winter wheat. Their adoption in semiarid or water-limited regions is limited because cover crops may reduce plant-available water for the main crops. Proper management including early termination and species selection are strategies to grow cover crops in water-limited regions. Although establishment and management can be a challenge in some soils, cover crops provide many soil and environmental benefits.

Soil Conditioners

Soil conditioners are products that are applied to control water erosion and improve soil properties. Some of the conditioners used to reduce water erosion include PAMs, phosphogypsum, and flue gas desulfurization (FGD) gypsum. These conditioners have not been widely used in agricultural lands although they are receiving increased attention as potential erosion control practices. Phosphogypsum and FGD are by-products of phosphate fertilizer manufacturing and generation of electricity from coal-fired power plants, respectively. These two conditioners have similar properties to gypsum and can be used in combination with PAM for soil erosion control. Phosphogypsum and FGD are applied to soil in larger quantities than PAM to achieve similar results. The FGD is a relatively new by-product that is being evaluated for erosion control.

PAMs come in different formulation types (dry granular beads, blocks, powders, and liquid). PAMs have been used in construction sites or disturbed soils, and in furrow- and sprinkler-irrigated soils. Application rates of PAM can vary depending on the soil-specific conditions (i.e., soil slope and texture), but application at 10 or 20 kg ha^{-1} can significantly reduce soil erosion in gently sloping soils. PAMs can reduce soil loss by as much as 90% and increase the infiltration rates by as much as 50% in furrow-irrigated croplands (Sojka *et al.*, 2004).

PAMs applied to the soil surface reduce water erosion by stabilizing exposed soil aggregates, maintaining the integrity of soil macropores, reducing surface sealing and crusting, and promoting flocculation of suspended sediment. These mechanisms increase water infiltration, reduce runoff and soil loss, and reduce turbidity in runoff water resulting from rain or irrigation. Application of PAM is more effective at reducing soil loss than runoff as it stabilizes aggregates and reduces their detachment. PAMs may not improve soil structure or aggregation like organic amendments (e.g., green manures, crop residues, and compost) do, but they stabilize the exposed soil.

Performance of PAM will depend on soil properties and companion management practices (Flanagan *et al.*, 2002). Soils with low clay and organic matter concentration may respond better to PAM application as PAM particles may interact more with fine particles. PAM's effectiveness and longevity decrease with increasing soil slopes and rainfall intensities because of greater concentrated flow and high runoff transport capacity. Combined application of PAM with phosphogypsum, FGD, and other conditioners may reduce water erosion more than the application of each product alone.

Phosphogypsum, gypsum, and FGD can complement PAM functions. Application of PAM stabilizes soil aggregates but conditioners, such as phosphogypsum, gypsum, and FGD, which have electrolytes, can chemically react with soil particles and promote soil aggregation. Recent studies across a wide range of soil types and climates have shown that application of phosphogypsum, PAM, and FGD can reduce runoff and soil loss (Cochrane *et al.*, 2005; Truman *et al.*, 2010; Rhoton and McChesney, 2011). These studies suggest that FGD application can be recycled into agricultural fields for erosion control. However, although the erosion control potential of FGD appears high, possible presence of trace elements (Hg and As) and their associated risks should be investigated more (Rhoton and McChesney, 2011).

Conditioners are not a substitute to soil conservation practices but should be used as companions to other practices. For example, PAM can be used as temporary stabilization practices in disturbed soils until a permanent surface cover is established. Cost of PAM technology for controlling soil erosion can be lower than that of construction of mechanical structures (e.g., sediment retention basins), but repeated PAM applications may increase the total cost.

Summary and Concluding Statements

The soil erosion process of sediment entrainment resulting from fluid pressures acting to detach and transport erodible soil particles has been extensively investigated for both wind and water. The resulting knowledge relating soil erosion mechanisms to fluid volume and velocity sufficient to exert the threshold energy for overcoming soil shear resistance has led to management practices for controlling erosion. Many contributing factors were linked to the overall complex soil erosion process using both empirical and mechanistic approaches. The resulting integration of those factors describes soil erodibility, wind or water erosivity, and potential soil and crop management avenues for controlling soil erosion.

Controlling soil erosion by management is generally directed at decreasing the energy of wind or water by limiting their velocity through decreased soil slope for water and through barriers for intercepting wind and raindrop impact. The erosive effects of both wind and water are cumulative with increasing distance because of greater transport capacity of increasing runoff water volumes or the intensifying downwind soil saltation and surface creep that produces soil avalanching. Soil stabilization reduces erosion through management practices resulting in aggregates that resist water degradation and transport or exceed the particle size transportable by wind. Soil protection prevents erosion through crop management practices that promote, for example, residue barriers to intercept the impact of saltating soil grains and raindrops. The common characteristics of soil entrainment and any countering management for both wind and water erosion agents often use common conservation practices.

Successful conservation practices include modifying field features, using tillage, and managing crop rotations for cover or residue retention. For example, fields are managed with terraces on a contour to reduce runoff that transports soil; however, reducing runoff also increases available soil water for greater potential crop biomass production that can be directed to increasing soil organic carbon. Tillage practices for wind erosion control produce large aggregates to resist surface erosion or crosswind ridges to trap saltating soil grains. Similar ridges formed along an elevation contour effectively control water erosion by redirecting runoff water movement along almost negligible slopes to prevent rill formation. Cover crops or residue management simply provide a barrier at the soil surface to intercept the impact of raindrops or saltating soil grains and disrupt seal formation or abrasion resulting in greater runoff or erosion susceptibility. These examples of conservation practices represent only a fraction of the available management technology that has matured since the catastrophic erosion conditions when soil conservation in the US was first investigated. The mature erosion-control technology limits the risk of similar erosion reoccurring.

Soil erosion processes are essentially unchanged and can be managed successfully using established conservation practices so that risks of resuming soil erosion at the catastrophic rates are unlikely. One significant caveat related to recurring soil erosion is the impact of potential climate change whether a natural, but infrequent, occurrence or an anthropogenical result. Climate change affecting temperature and precipitation will necessarily stabilize or destabilize the soil through modified soil properties. For example, soil organic matter content that improves aggregation is inversely related to increasing soil temperature, which suggests greater potential erodibility in the event of prolonged warming trends. Alternatively, the amount of precipitation is directly related to soil organic matter and would also shift soil erodibility in a corresponding manner. Climatic temperature and precipitation conditions are interrelated as is their potential impact on soil conservation.

Severe drought can limit or prevent vegetative growth but, as observed by Chepil and Woodruff (1963), drought was not exclusively responsible for severe wind erosion. Erosion events combined the effects of drought-limited vegetative growth with various destabilizing soil disturbances, including grazing and tillage. The resulting soil condition featured critically depleted organic carbon or destroyed residue cover that increased soil erodibility. Nevertheless, soil erodibility does increase with the duration of drought and diminishes only after a minimum of two consecutive years of favorable precipitation and vegetative growth. Recent investigations characterizing more erodible fine soil material found microbial communities capable of tolerating the extreme ecological conditions of desiccation or radiation consistent with drought conditions in lieu of those important to C and N cycling, which are found in less erodible coarse soil particles (Gardner *et al.*, 2012). Although the knowledge of effective soil conservation practices is unaffected by climatic concerns and mature soil erosion control technologies will follow best known management applications, concern for the risk of recurrent catastrophic erosion cannot be disregarded.

Glossary

Chlorosis Yellowing or lighter shade of green.
Immobile nutrient The immobile elements cannot translocate within the plant to meet need and therefore their deficiency typically occurs in the younger leaves first.
Internode The distance on the stem between leaves.
Interveinal Between the leaf veins.
Meristem The growing point of a plant.
Mobile nutrient A mobile element is able to translocate to areas of the plant with the most need. Typically, mobile elements move from the older or lower leaves to the upper or younger leaves to support new growth.
Necrosis Browning or dying of plant tissue.

Introduction

Soil fertility and plant nutrition encompasses the management of essential elements necessary for plant growth, typically to achieve selected management objectives. Although soil fertility plays a vital role in natural systems, the scope of this article is limited to plant production for human uses (e.g., food, feed, fiber, energy, and landscape esthetics). An element is considered essential if it is required for plant metabolism and for completion of the plant's life cycle (Epstein and Bloom, 2005; Havlin *et al.*, 2005). Typically, 17 elements are considered to meet these criteria and they are divided into macro- and micronutrients (Table 1). This division is based on their relative abundance in plant tissue rather than on their necessity for plant growth. Macronutrients are generally present in plant tissue at concentrations above 0.2%, whereas micronutrients are present below 0.01% (dry weight basis). Carbon (C), hydrogen (H), and oxygen (O) are derived from carbon dioxide (CO_2) and water (H_2O), which are transformed through photosynthesis to produce carbohydrates and are, therefore, present in the highest concentrations of any element in plant tissue. They are not, however, considered mineral elements and are almost always available in amounts necessary for their direct use in complete plant metabolism.

The essential mineral macronutrients can be divided into primary macronutrients, which include nitrogen (N), potassium (K), and phosphorus (P), and secondary macronutrients, calcium (Ca), magnesium (Mg), and sulfur (S). The eight micronutrients are copper (Cu), manganese (Mn), iron (Fe), boron (B), nickel (Ni), molybdenum (Mo), chlorine (Cl), and zinc (Zn). Other mineral elements may be essential for some plants or benefit crop quality or growth, although not being essential for metabolic processes or completion of the plant's life cycle; often these elements are referred to as 'beneficial elements.' Beneficial elements include cobalt (Co), sodium (Na), silicon (Si), selenium (Se), and vanadium (V). Silicon is present in concentrations on the order of some of the macronutrients in many plant tissues and has beneficial properties but is not generally considered essential to metabolic processes or the life cycle of any plants outside the family Equisetaceae (Epstein, 1994). However, there is an emerging school within the soil fertility research community that believes it may be more essential than previously thought.

Many other elements are taken up by plants in varying degrees but are not considered essential as defined above. Both essential and nonessential elements may be toxic to plants if accumulated at high enough concentrations to interfere with metabolic functions. Therefore, soil fertility and plant nutrition as a discipline encompasses management of these essential elements in the soil to provide them in adequate or sufficient amounts for plant metabolic processes and reproductive activities to be completed. Optimum soil fertility requires not only adequate quantities of the essential elements but also that they be in a form and location available for plant uptake and therefore optimum plant nutrition.

Soil Fertility Management

History of Soil Fertility and Plant Nutrition

Actively managing soil nutrients to provide optimum plant nutrition has been a core practice of agricultural production throughout human history. For many centuries agricultural production relied on recycling of organic residuals, such as manure and crop residues. Industrialization and population growth of the nineteenth century demanded increased agricultural production and coincided with the development of commercially produced P fertilizers. Providing adequate P fertilization allowed the true potential of N fertilization to be realized, and industrial production of inorganic N fertilizer soon followed with the development of the Haber–Bosch process in 1909. Stewart *et al.* (2005) estimated that N, P, and K fertilizers likely account for 40–60% of yield in the United States and England and much higher in the tropics. Industrially fixed N fertilizer has been estimated to account for 40–48% of the world's protein supply (Erisman *et al.*, 2008).

In a macrosense, the relationship between the development of commercial P and N fertilizers reflects one of the guiding premises of soil fertility explicitly stated as the theory of the minimum developed by Carl Sprengel in 1828 and popularized as 'Liebig's law of the minimum,' which states that

 doi:10.1016/B978-0-444-52512-3.00249-7

Table 1 Essential nutrients and beneficial elements, their ionic plant-available forms, and their role in plant growth and development

	Element(s)	*Form taken up by plants*	*Role*
Nonmineral macronutrients	Carbon (C)	CO_2	Directly involved in photosynthesis
	Hydrogen (H)	H^+, OH^-, and H_2O	
	Oxygen (O)	O_2	
Mineral primary macronutrients	Nitrogen (N)	NH_4^+ and NO_3^-	Found in chlorophyll, nucleic acids, and amino acids. Major component of proteins and enzymes controlling most biological processes
	Phosphorus (P)	HPO_4^{2-} and $H_2PO_4^-$	Component of adenosine di- and triphosphate (ADP and ATP), which is essential for energy storage and transfer. Essential component of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Important for most plant development processes and component of plant tissues, particularly concentrated in seeds
	Potassium (K)	K^+	Not incorporated in cell structure. Found in ionic form. Regulates water usage and provides disease resistance and stem strength. Involved in photosynthesis, drought tolerance, winter hardiness, and protein synthesis
Mineral secondary macronutrients	Calcium (Ca)	Ca^{2+}	Essential for cell elongation and division. Required for root and leaf development and function and formation of cell membranes and walls (e.g., Ca pectate). Involved in activation of enzymes
	Magnesium (Mg)	Mg^{2+}	Primary component of chlorophyll and important to photosynthesis. Component of ribosomes required for protein synthesis. Involved in phosphate metabolism, respiration, and enzyme activity
	Sulfur (S)	SO_4^{2-}	Required for synthesis of and contained in amino acids, which are essential for protein formation. Promotes nodulation in legumes. Involved in development of enzymes, seed production, and chlorophyll formation
Mineral micronutrients	Copper (Cu)	Cu^{2+}	Enzyme catalyst and required for chlorophyll formation
	Manganese (Mn)	Mn^{2+} and Mn^{4+}	Involved as catalyst and in activation for enzyme systems. Serves as a catalyst in chlorophyll synthesis
	Iron (Fe)	Fe^{2+} and Fe^{3+}	Catalyst in chlorophyll synthesis. Involved in oxidation and reduction reactions during respiration and photosynthesis
	Boron (B)	H_3BO_3, BO_3^-, and $B_4O_7^{2-}$	Essential for germination of pollen, growth of pollen tubes, seed and cell wall formation, and development and growth of new cells in meristematic tissue. Associated with translocation of sugars, starches, N, and P
	Nickel (Ni)	Ni^{2+}	Component of the urease enzyme. Essential for plants supplied with urea and for those in which ureides are important in N metabolism
	Molybdenum (Mo)	MoO_4^{2-}	Required for synthesis and activity of the enzyme system that reduces NO_3^- to NH_4^+ in plants (nitrate reductase). Essential for N fixation by rhizobia
	Chlorine (Cl)	Cl^-	Involved in plant energy reactions, plant–water relationships, regulation of stomata guard cells, drought and disease resistance, enzyme activation, and cation transport in plants
	Zinc (Zn)	Zn^{2+}	Involved in the synthesis of plant growth compounds and the enzyme system. Necessary for the production of chlorophyll, carbohydrates, and growth hormones
Beneficial elements	Cobalt (Co)	Co^{2+}	Complexes with N and synthesis of vitamin B_{12}
	Sodium (Na)	Na^{2+}	Essential for halophytic plants partially replacing K^+
	Silicon (Si)	H_4SiO_4	Possibly photosynthesis regulation enzyme activity
	Selenium (Se)	SeO_3^{2-} and SeO_4^{2-}	Not essential to plants but required by animals
	Vanadium (V)	VO_3^-	May be involved in fixation by rhizobia or biological oxidation–reduction reactions

production is limited by the amount of the most limited nutrient relative to the plant's need (Jungk, 2009). In other words, regardless of how much N is added, yield would be limited if P were not available in sufficient quantities. Once adequate P was provided through fertilization, after the development of P fertilizers, only then could additional yield be attained through N fertilization. Through the rigorous application of the scientific method, Sprengel and his contemporaries launched the discipline of soil fertility and plant nutrition to meet the world's growing demand for food. Perhaps Sprengel's greatest contribution was the understanding that mineral nutrients external to the plant were required for

plant growth. Identifying the essential elements and understanding that they must be provided external to the plant was a fundamental shift in agricultural production. Before Sprengel's work, some nutrients were supplied through recycling of crop residues and manures, and N could be provided through N-fixing crops in rotation; however, the majority of nutrients were lost from the system (due to system inefficiencies) and crop production was limited and agricultural lands were often depleted after a few years of cropping. Daniel Webster understood the importance of conservation of matter to this system when he stated "it is upon this fundamental idea of constant production without exhaustion, that the system of English cultivation, and indeed, of all good cultivation is founded" in his lecture 'On the Agriculture of England' presented 13 January 1840 (Webster and Everett, 1851).

The development of the concepts of soil fertility and plant nutrition and the realization that nutrients had to be supplied externally through fertilization to avoid the 'exhaustion' of the soil in the early nineteenth century by a new breed of soil chemists and agronomists helped to avoid the Malthusian Catastrophe, predicted in 1798 by Thomas Robert Malthus. These principles underpinned the 'Green Revolution' of the twentieth century. Tilman *et al.* (2002) estimated that, between 1960 and 2000, global cereal production doubled while global N use increased sevenfold and P use increased three and one-half fold. However, this increase in production and concomitant increase in fertilizer use has not come without cost. There are questions regarding the environmental sustainability of continuing to fix N and mine P for fertilizer, both due to resource availability (of energy and the mined minerals) and concerns about the impact of N and P losses from agriculture to surface and groundwaters (Cordell *et al.*, 2009; Dawson and Hilton, 2011). As a result, although managing soil nutrients for optimum plant nutrition and yield continues to be a pressing concern in light of global population growth, the management of nutrients in an efficient manner to protect resources is an important component of any discussion of soil fertility and plant nutrition.

Soil Fertility Evaluation

Modern soil fertility management integrates the disciplines of soil chemistry, soil biology, soil physics, and plant science to develop practices that provide the essential elements required for plant growth in sufficient quantities to maximize production while providing for environmental protection. In agricultural systems, this may mean optimizing production for economic return, whereas in other systems, such as phytoremediation or landscaping, there may be other goals that should be accounted for when planning a soil fertility strategy (e.g., rapid stand establishment, sufficient ground cover, or species biodiversity). Beyond management of soil nutrients, soil fertility must also address factors contributing to the soil's ability to supply nutrients and the plant's ability to efficiently utilize nutrients present. Optimum soil nutrient status alone will not provide for optimum system performance as numerous other factors influence plant nutritional status. Factors such as soil pH, moisture status, salinity, and physical condition as well as biotic stressors have a profound effect on a plant's interaction with nutrients. These factors are covered elsewhere in this encyclopedia and should be considered integral to comprehensive soil fertility and plant nutrition management. Most soil fertility management strategies have three key components: soil fertility assessment, nutrient recommendations, and performance evaluation to inform future decisions.

The goal of any soil fertility and plant nutrition program is to holistically address the factors influencing crop nutrient utilization in order to maximize plant performance. Therefore, the ultimate goal is to have each of the essential nutrients present in plant tissue at a sufficient concentration to support metabolic functions of the plant. For each essential element, there is a critical concentration within plant tissue above which added nutrients will not increase plant performance but may increase tissue concentrations of that nutrient. Below the critical concentration, plant performance will likely suffer due to a deficiency of that nutrient. Beyond the sufficiency range, concentrations of certain essential elements in plant tissue may be toxic and decrease plant performance; this range is often referred to as excessive or toxic range. Figure 1 shows an idealized response curve with the critical concentration and the deficient, sufficient, and excessive or toxic ranges identified. The actual concentrations for each nutrient will vary withplant species, plant part, and growth stage.

Soil fertility assessment is a critical component to soil fertility management. The traditional goal of this assessment has been to evaluate the ability of a soil to supply the essential nutrients for optimum crop performance. Performance may be determined by yield, crop quality, or some other metric depending on management goals. Beyond quantifying essential elements present, soil fertility assessment should also evaluate other factors that might influence the soil nutrient supply to the plant, such as pH or compaction. Increasingly, modern soil fertility assessment also accounts for the potential

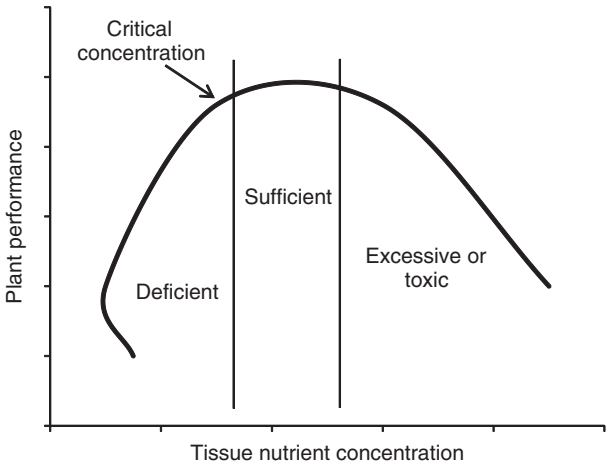

Figure 1 Nutrient concentration in plant tissues as it relates to plant performance. Below the critical range plants are considered deficient. The range where nutrient concentration in the tissue increases, but performance does not, is considered the sufficient range. At some point beyond the sufficiency range, excessive nutrient concentrations can limit plant performance and this is considered the excessive or toxic range.

environmental impact of soil nutrients. There is a wide range of techniques used to assess soil fertility. Generally, soil fertility assessment can fall into three broad categories: direct assessment of soil physical or chemical characteristics; quantification of essential elements in plant tissue; or evaluation of plant response to soil nutrient status. A key component of any soil fertility assessment is the interpretation of results to generate fertilizer recommendations. Typically, one analyzes the nutrient content of soil or tissue samples or evaluates the expression of deficiency or sufficiency in plants and then interprets these findings to recommend rates of nutrient to apply to avoid or correct deficiencies.

Soil analysis

The first broad category of soil fertility evaluation is soil testing or the chemical extraction of soil nutrients to estimate their plant availability. Research in soil testing began in the nineteenth century following Sprengel's work, but systematic research into soil testing and plant nutrient status began in earnest in the 1920s. With the development of more advanced analytical capabilities, organized soil testing programs were established in the United States in the 1940s. Peck and Soltanpour (1990) defined soil testing as "…rapid chemical analyses to assess the plant-available nutrient status, salinity, and elemental toxicity of a soil…a program that includes interpretation, evaluation, fertilizer and amendment recommendations based on results of chemical analyses and other considerations." This definition identifies four key components of a soil fertility assessment. The first is an assessment of the soil nutrient status, typically through a chemical extraction of soil or plant tissue. However, the other three components are equally important: the results of the nutrient quantification must be interpreted to provide an index of the relative proportion of the nutrient present that is available for plant use; they must then be evaluated in the context of potential plant response to fertilizer; and finally they must be translated into a recommendation for the amount, form, placement, and timing of a fertilizer application to provide optimum nutrient status for crop growth.

The soil test typically extracts a portion of the total amount of the element present. The amount extracted is proportional to the amount that is available for plant uptake. A response curve is then defined, typically through empirical laboratory, greenhouse, or field experiments, which predicts the potential for crop response to added fertilizer. Therefore, a soil test provides a relative index of potential responsiveness that forms the basis of a fertilizer or lime amendment. Interpretation of soil test results follows closely the definition provided previously for plant nutrition sufficiency (**Figure 1**). An idealized soil testing response curve is provided in **Figure 2**. Generally, no response to added fertilizer is expected above the critical soil test level identified in **Figure 2**. The relative index of soil nutrient supply capacity varies according to recommendations system, but generally the scale is divided into areas, 'below optimum,' 'optimum,' and 'above optimum' or 'excessive' nutrient concentration. A yield response to added fertilizer is expected when soil test levels are below optimum (i.e., below the critical threshold). Starter or maintenance levels of fertilizer may be recommended in the optimum range. Some nutrients may cause environmental risk or plant toxicity above the optimum range.

Nutrient recommendations are determined by soil test results; however, even when two labs use the same methods and generate equivalent results, their nutrient recommendations may differ. These disparities arise due to differences in soil test interpretation and recommendation philosophies. Over the years, three basic philosophies have emerged. These include the sufficiency approach, the build and maintain approach, and the base cation saturation ratio (BCSR) theory. Both the sufficiency approach and the build and maintain approach

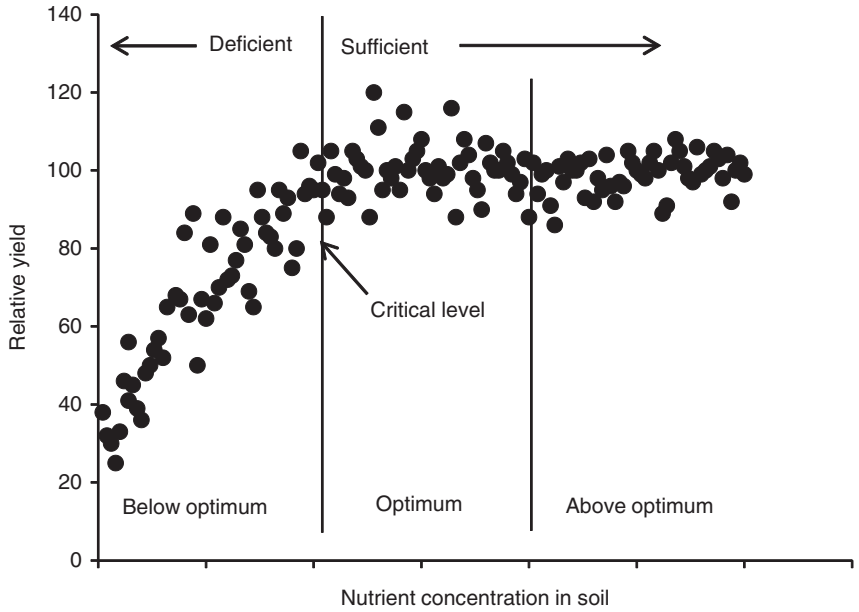

Figure 2 Empirical relationships are defined between soil nutrient concentrations and yield response. As the soil concentration increases less fertilizer is required to optimize yield.

follow the general concept that there are definable critical levels of nutrients in soil and that below this level crops are likely to respond to additional applied nutrients. When nutrient concentrations are in the optimum range, just above the critical level, there is a low probability of crop response with further addition of that nutrient. With the build and maintain approach, fertilizer recommendations are made with the goal of building the soil's nutrient levels into the optimum range, then maintaining these levels by applying nutrients at rates that approximate crop removal. The sufficiency approach is a more conservative philosophy where nutrient recommendations are intended to only meet crop needs and not build soil fertility. No nutrients are recommended above the critical soil test level. The sufficiency approach is designed to 'feed the crop,' whereas the build and maintain approach is designed more to 'feed the soil.' In theory, the sufficiency approach is a more profitable system because fertilizer is applied only when there is likely to be an economic return. However, in practice the sufficiency approach is also more risky due to the inherent uncertainty associated with soil testing.

The third philosophy, the BCSR theory, promotes the idea that maximum yields can only be achieved by creating a balanced ratio of Ca, Mg, and K in the soil. The concept is rooted in the work conducted by Dr. Firman Bear and his colleagues at the New Jersey Agricultural Experiment Station in the 1940s (Bear and Prince, 1945; Bear and Toth, 1948). Bear's work showed that the luxury consumption of costly fertilizer K by alfalfa could be reduced by applying high rates of relatively low-cost Ca (as ground gypsum or calcitic lime). As an aside, Bear also pointed out that another effective strategy to reduce luxury consumption of K by alfalfa was to use split applications of moderate doses of fertilizer K rather than infrequent high rates (a best management practice still recommended today). Bear and his colleagues suggested that there were ideal ratios of Ca, Mg, and K; however, they provided no data to support these claims, so it is unclear how they were developed.

Around the same time, Dr. William Albrecht and his colleagues at the University of Missouri began to investigate the BCSR theory. This work and its findings are summarized in the Albrecht Papers (Albrecht and Walters, 1996). They conducted a series of experiments on soils and soil minerals amended to achieve a wide range of Ca:Mg:K ratios. Based on this work, Albrecht suggested that a balanced soil should have a cation saturation of 60–75% Ca, 10–20% Mg, and 2–5% K. It is unclear how Albrecht derived these values; in fact, much of the data Albrecht and his colleagues published illustrated that optimum yields occurred over a wide range of Ca, Mg, and K ratios. Further, careful evaluation of the work a number of years later revealed several fundamental flaws in the methods Albrecht and his colleagues used. Over the years, a number of soil scientists have evaluated the BCSR theory (see review by Kopittke and Menzies, 2007). This work has failed to support claims of BCSR theory and has illustrated that using it to manage soil fertility results in inefficient use of both capital and natural resources. Nonetheless, the importance of attaining an ideal BCSR, especially pertaining to the importance of very specific Ca:Mg ratios, continues to be promoted. These claims include the following: improved soil structure, reduced weed pressure, increased resistance to insect and disease, and reduced leaching of other nutrients. There are no research data that support these claims.

Most of the guidelines developed by US Land Grant Universities and used by both public and private soil test labs follow a combination of the sufficiency and build and maintain approaches, the goal being to provide adequate, but not excessive, levels of essential nutrients to promote healthy plant growth. The nutrient guidelines are intended to help growers optimize crop yield and quality, maximize return on fertilizer investment, and minimize nutrient losses to the environment.

Plant tissue analysis

Soil fertility evaluation does not rely on soil testing alone. Visual diagnosis of plant nutrient deficiencies, in-field measurements of plant nutrient status, laboratory analysis of tissue nutrient concentrations, and remote sensing of plants can all be valuable tools in identifying plant nutrient deficiencies, so that they can be corrected or prevented. Soil testing can be used before planting or in season to guide nutrient applications. Plant tissue analysis can be used in season to identify or confirm visually observed nutrient deficiencies (Table 1). When combined with a soil testing program, plant tissue sampling and testing or analysis can be very useful in determining the cause of visual deficiency symptoms. There are many tools available for in-field plant analysis, including the leaf chlorophyll meter that measures light absorption at specific wavelengths and handheld or equipment-mounted photometers that measure light reflectance. These tools are often used to calculate various vegetative indexes based on the ratio of light reflectance at different wavelengths to estimate sufficiency or predict nutrient need through more advanced algorithms. However, these types of diagnostic tools are beyond the scope of this article, which is limited to traditional visual diagnosis and plant tissue analysis.

It is important to take a holistic approach to soil fertility management and interpret tissue test results in the context of soil test results, field conditions, plant health, and other potential plant stresses. Many factors can influence relative nutrient availability or the ability of a plant to take up available nutrients, causing a nutrient deficiency to be expressed visually or in tissue nutrient concentrations. For example, a grower may visually identify P deficiency in a corn field due to the presence of stunted, purple-colored plants. If only a tissue sample was collected and it showed P deficiency, the grower may then conclude that additional P is required. However, a soil sample may reveal that there was adequate P in the soil, but that the pH was low, limiting P availability, evaluation of the whole plant could reveal that a root disease, such as Pythium root rot, induced the above-ground P deficiency symptoms. In either case P fertilizer was not truly required, even though a tissue test alone would have indicated that it was. There are many examples where soil nutrient concentration is not the culprit of a deficiency identified visually or through tissue analysis, so caution should be applied when interpreting plant tissue concentrations. A valuable application of tissue testing is to confirm nutrient deficiencies within problem areas observed in a field. For example, many nutrient deficiencies result in plants exhibiting interveinal chlorosis. If the symptom is exhibited sporadically across the field, tissue samples can be collected from within the affected regions and

compared with results from samples collected from unaffected regions. This comparison along with soil test results from both areas can be used to narrow which specific nutrient might be causing the symptoms. However, it is important to remember that it is not enough to identify a nutrient deficiency, the cause must also be determined before corrective action can be taken. It does no good to apply a nutrient that is deficient if soil compaction, pH, root disease, or other problems are limiting uptake of that nutrient by the crop.

The results of tissue analysis are highly dependent on how and when the sample was collected. Some of the essential elements are considered mobile nutrients within plants because they can be translocated from mature plant parts to the areas of the plant that are actively growing (meristem), so that deficiencies will occur initially in the older parts of the plant. Conversely, immobile nutrients cannot translocate and therefore deficiency symptoms are typically exhibited initially in the youngest part of the plant. **Table 2** provides a list of the essential mineral elements, their relative mobility within the plant, relative and average concentration in plant tissue, and typical deficiency symptoms. The relative concentrations presented in **Table 2** are provided to give perspective on the relative proportion of each nutrient in plants, where the average concentration presented for each nutrient is divided by the average concentration of Mo in plant tissues (Havlin *et al.*, 2005). As the sufficiency range for nutrient concentrations varies greatly between plants, the part of the plant sampled, and the timing of sample collection, it is best to refer to optimum ranges supplied by local soil and plant tissue testing laboratories.

Most laboratories that provide soil and plant tissue testing services provide instructions on which part of the plant should be sampled and the appropriate timing for tissue sampling. For example, when sampling corn seedlings ($<$ 12 in. tall), the entire plant should be sampled by cutting it off approximately 1 in. above the soil surface; for vegetative growth stages the uppermost collared leaf should be sampled, and at tasseling the ear leaf should be sampled. Once the plant enters reproductive stages, some essential nutrients begin to move to the seed or fruit from other parts of the plant and therefore a tissue sample taken after initial flowering may not accurately represent nutrient uptake and availability. Similarly, tissue sampling and tissue test results are often used inappropriately to determine fertilizer need. In corn, for example, during the first two vegetative growth stages (up to V2 or two fully collared leaves) the plant utilizes very little soil N and relies primarily on N provided by the seed. Therefore, tissue samples collected at this time provide very little value in terms of determining additional N need. Once the plant reaches the rapid growth stage ($\approx$V4 – tasseling), tissue N concentrations fluctuate

Table 2 Essential elements, their mobility, relative and average concentration in plants, and common deficiency symptoms

Essential element	*Mobility*	*Concentration in plants*[a]		*Common deficiency symptoms*
		Relative	*Average*	
Nitrogen	Mobile	1 000 000	1.5%	Stunted chlorotic plants with increased susceptibility to stress. Early maturity
Phosphorus	Mobile	30 000	0.2%	Overall stunted plant and poor root development with purple to reddish color
Potassium	Mobile	400 000	1.0%	Scorching or firing along leaf edge. Deficient plants grow slowly with poor root development. Weak stalks with lodging common and small seed or fruit. Low stress tolerance
Calcium	Immobile	200 000	0.5%	Poor root growth with roots often turning black and rotting. Failure of terminal buds and apical tips of roots to develop
Magnesium	Mobile	100 000	0.2%	Leaves show a yellowish, bronze, or reddish color while leaf veins remain green
Sulfur	Somewhat mobile	30 000	0.2%	Chlorosis of longer leaves or chlorotic stunted plants. Resembles N deficiency; however, upper leaves tend to show deficiency first
Copper	Immobile	100	6 ppm	Reduced leaf size. Uniformly pale yellow leaves. Leaves lack turgor and may develop bluish green color, become chlorotic, and curl. Flower production fails
Manganese	Immobile	1 000	50 ppm	Interveinal chlorosis. Appearance of brownish black specks
Iron	Immobile	2 000	100 ppm	Interveinal chlorosis. In the case of severe deficiency the entire leaf may turn white
Boron	Immobile	2 000	20 ppm	Reduced leaf size and deformation of new leaves. Interveinal chlorosis if deficiency is severe. Possibly distorted stems. May cause flower or fruit abortion, poor grain fill, and stunted growth
Nickel	Mobile	0.1	0.01 ppm	Limited information available on deficiency symptoms
Molybdenum	Immobile	1	0.1 ppm	Interveinal chlorosis, wilting, and marginal necrosis of upper leaves
Chlorine	Mobile	3 000	100 ppm	Chlorosis of upper leaves and overall wilting of plant. Deficiencies may show in upper leaves, even though mobile
Zinc	Immobile	300	20 ppm	Shortened internodes between new leaves, death of meristematic tissue, deformed new leaves, and interveinal chlorosis

[a]Relative nutrient concentrations are expressed on the basis of their concentration relative to molybdenum. Concentrations are expressed on a dry matter mass basis and adapted from Havlin, J.L., Beaton, J.D., Tisdale, S.L., 2005. Soil Fertility and Fertilizers: An Introduction to Nutrient Management. Upper Saddle River, NJ: Pearson Prentice Hall.

wildly due to the rapid growth of the plant and variation in uptake relative to tissue development. Therefore, recommendations based on tissue samples collected at this time may be highly unreliable. Owing to the many factors that influence nutrient concentrations in tissues, great caution should be taken when interpreting tissue sample results and trying to formulate fertility recommendations. Their best utility is in comparing 'good' and 'bad' areas within the same field as they were exposed to the same growing and management conditions.

A unique tissue test that has gained popularity recently is the corn stalk nitrate test (CSNT). The CSNT is an end-of-season test that provides a retrospective assessment of the season's nitrogen management. Corn plants show no visual evidence of overfertilization. The CSNT can provide this information, allowing producers to know when a field received more nitrogen than needed for maximum yield. After pollination, nitrogen from the leaves and stalk is mobilized and transported into the developing grain. During this process and after black layer, nitrate uptake from the soil into the plant also continues. If more nitrogen is available to the plant than needed for maximum yield, nitrate accumulates in the stalk, particularly the lower stalk. The CSNT is a robust test that is able to identify when N was available in excess of crop need and along with other information on N management it can be used to fine tune N management in future growing seasons (Binford *et al.*, 1990). However, the range of stalk nitrate concentrations is very narrow in the optimum and below optimum ranges and therefore of limited utility in accurately identifying when very little N is available.

Soil Characteristics Contributing to Nutrient Supply

Soil Mineralogy

Soil mineralogy is one of the dominant soil properties controlling the amount of nutrients present in the root zone and the rate at which they are made available to plants. Nutrient supply is simply the quantity of nutrients held onto the soil particle surface, either as a result of natural geologic parent material or anthropogenic activity (i.e., fertilization). A simple but important concept regarding the role of soil mineralogy in soil fertility and plant nutrition is the notion that plants can take up nutrients only from solution. The focus is often on the amount or 'quantity' of nutrients present in the soil, but the ability of a soil to supply nutrients is also determined by the soil's ability to potentially release those nutrients into the soil solution where they are then available to the plants. The concentration of the nutrient that is found in or easily dissolves or desorbs into solution is known as the 'intensity.' The quantity–intensity relationship for a given soil is a measure of the soil's buffering capacity with respect to that nutrient. An example of quantity–intensity relationship is shown in Figure 3.

In general, the quantity is some measure of the total nutrient supply that is not necessarily 100% labile. This could be the nutrient concentration determined by a total digestion under strong acid and heat, or some other type of harsh extraction. However, the intensity is the concentration of that same nutrient that is labile or in solution, often estimated with

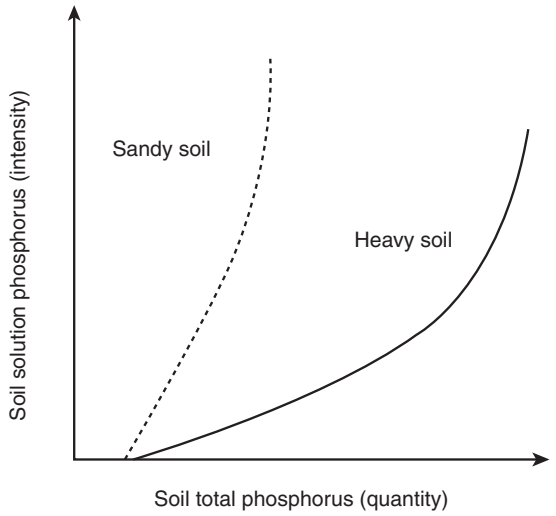

Figure 3 Example of quantity–intensity (Q/I) curves for soil phosphorus for sandy and 'heavy' (high clay content) soils.

ion-exchange membranes or water extraction analysis. The quantity–intensity curve varies depending on the nutrient and chemical characteristics of the soil, particularly the mineralogy and pH. Essentially, the quantity–intensity curve describes the ability of the soil to supply the solution with the nutrient. As it is not feasible to determine the quantity–intensity relationship in every case where a nutrient recommendation is required, it is the goal of agronomic soil testing to provide some of this information using rapid and affordable techniques.

The slope of the quantity–intensity curve is considered to be the buffering capacity for the specific nutrient and soil depicted. In general, as the soil quantity (i.e., supply) of the nutrient increases, the ability of that nutrient to be released into solution increases. However, note that the slope of this curve is not generally constant; this is especially true for certain nutrients that are strongly bound to the soil, such as trace metals or P onto Fe oxide minerals. In such cases, the soil shows a limited capacity to release the nutrient into solution when the quantity is low, but as the quantity becomes larger, a given increase in quantity will result in a greater increase in intensity, or solution concentration, compared with the case where the quantity is lower. In other words, at higher quantity concentrations, further increases in the quantity through fertilization will yield more efficient release of the nutrient into solution. This is why for certain soils it is important to 'build up' P concentrations so that plants can have access to soil P.

Permanent-charge versus variable-charge minerals

As previously mentioned, soil mineralogy can have a profound impact on the quantity–intensity relationship. With regard to the mechanism by which soil minerals retain nutrients, minerals can be classified into two different groups: permanent-charge (or variable potential) minerals and variable-charge minerals. Permanent-charge minerals retain a constant negative charge regardless of solution conditions (i.e., pH and ionic strength). Permanent-charge minerals obtain their inner-layer charge from isomorphous substitution occurring in 2:1 clay minerals. In addition to possessing negative charge, for a

mineral to sorb a cation nutrient from solution, the negative charge must be physically accessible to cations in solution. Thus, it is found that some minerals with high levels of permanent negative charge are unable to sorb many cation nutrients from solution, such as illite and biotite, as their inner layer is mostly clamped shut with K ions holding the layers together tightly. Instead, it is mostly vermiculite and montmorillonite that possess a permanent negative charge which is accessible to solution cations. In addition to vermiculite and montmorillonite, there are amorphous 2:1 minerals that possess accessible permanent negative charge; such minerals are most common in recently developed volcanic (Andic) soils. Zeolites (tectosilicates) are a group of soil minerals that possesses a large amount of accessible permanent negative charge but are not 2:1 minerals.

Permanent-charge minerals can retain only cation nutrients from solution, such as Ca^{2+}, Mg^{2+}, Ni^{2+}, K^{+}, Cu^{2+}, etc. However, variable-charge minerals can become positively charged depending on solution pH, which allows them to sorb anion nutrients, such as PO_4^{3-} and SO_4^{2-}. This variable charge occurs mostly on the terminal hydroxide groups located on the edges of 1:1 minerals (such as kaolinite) and Fe, Al, and Mn oxides or hydroxides (such as goethite and gibbsite). Although not a mineral, soil organic matter contains numerous variable-charged functional groups that behave similarly. Similar to the 2:1 minerals, there exists both crystalline and amorphous 1:1, oxide, and hydroxide minerals. Equations [1 and 2] show generic reactions where charge development occurs due to protonation or deprotonation of hydroxide groups.

Protonation of a metal hydroxide mineral resulting in a positively charged surface site (eqn [1]).

$$FeOH^0 + H^+ \leftrightarrow FeOH_2^+ \quad [1]$$

Deprotonation of a metal hydroxide mineral resulting in a negatively charged surface site (eqn [2]).

$$FeOH^0 \leftrightarrow FeO^- + H^+ \quad [2]$$

Note that the degree of each reaction can be quantified by a specific *k* value (i.e., reaction constant) for each mineral. Thus, as pH increases, the negative charge on the mineral surface increases, whereas the positive charge decreases, and when pH decreases the negative charge decreases and positive charge increases. For example, if the surface functional groups shown in eqns [1] and [2] were located on goethite, the *k* value would equal to $10^{6.2}$ and $10^{-11.8}$, respectively. As you would expect, this change in charge can impact the ability of the surface of variable-charge minerals to retain anion and cation nutrients. Each variable-charge mineral possesses a unique point of zero charge (PZC), which is the pH at which the net charge equals zero. When the pH is greater than the PZC of the mineral, the net charge on the mineral is negative. Note that this does not necessarily mean that there is no longer any positive charge; it simply means that there is more negatively charged sites than positively charged sites.

Ion-exchange reactions (nonspecific sorption)

Nutrient ions are attracted to sites of opposite charge located on minerals and organic matter, either permanent or variable charge. When ions bind to the mineral sites by weak electrostatic attraction (i.e., no direct contact with the surface), this is known as ion exchange. Ion exchange is characterized by a weak and reversible bond known as nonspecific sorption. Ions that bind by this mechanism can be easily and rapidly displaced by other ions of the same charge. This reversible nature of ion exchange is extremely important to both agronomic production and environmental quality. Specifically, if bonds retaining nutrient ions are excessively strong then there is less potential for them to be released into solution for subsequent nutrient uptake or transport. Yet the reversible nature of the ion-exchange reaction is still strong enough to prevent all nutrients from simply passing through the soil and directly to groundwater and surface water, being lost from the agroecosystem and having potentially negative implications.

Other characteristics of ion exchange include charge balance and selectivity. All ion-exchange reactions are charge balanced; for example, one mole of Ca^{2+} can exchange with 2 mol of K^{+}. This is why ion exchange and soil charge are typically quantified in units of equivalents, which is the same as a mole of charge (i.e., molecular weight normalized for valence of the ion). The selectivity of ion-exchange reactions has several implications. At equal concentrations, ions with a greater charge density are preferred over ions of lesser charge density. For example, Al^{3+} is preferred over Ca^{2+}, which is preferred over K^{+}. Similarly, K^{+} is preferred over Na^{+} because K^{+} has a greater charge density; although the two ions possess the same charge, K^{+} is a smaller ion due to a lower degree of hydration. Although ions of greater charge density are selectively sorbed over ions of lesser charge density, this is somewhat concentration dependent due to the fact that ion-exchange reactions are subject to Le Chatelier's principle (the equilibrium law that states if a system at equilibrium undergoes a shift in concentration the system will adjust to try and counteract the shift in equilibrium). For example, consider a soil system where K^{+} ions are sorbed to the clay surfaces and Ca^{2+} is added to the soil solution. For each mole of Ca^{2+} added to the system, two moles of K^{+} will be replaced and moved to the soil solution.

Although Ca^{2+} is selectively sorbed over K^{+} at equal concentrations, if the concentration of K^{+} becomes large enough, it can displace the Ca^{2+} at the surface (i.e., reverse reaction). Note that ion-exchange reactions are subject to the laws of thermodynamics and are quantified by the reaction constant *k*. As a result, if the concentration on one side of the reaction becomes much greater than the concentrations on the opposite side, the reaction will proceed toward the side with lower concentrations in order to equilibrate the system to maintain the reaction constant (Le Chatelier's principle). Thus, as a plant depletes the soil solution of nutrients, this offsets the balance between ions sorbed onto the surface and ions in solution, and Le Chatelier's principle tells that the ions sorbed onto the surface will desorb into solution in order to maintain equilibrium between the surface and solution. In this way, the soil serves as a 'nutrient warehouse' that acts to supply the solution for plants; one of the challenges of nutrient management is to resupply the warehouse when it becomes depleted.

The sum of all cation charges (equivalents) that are held onto the soil by the ion-exchange mechanism is the cation-exchange capacity (CEC). Likewise, the sum of all anion

Table 3 General description of the ability of cations and anions to bind by specific sorption, nonspecific sorption, or both

	Specific sorption (ligand exchange or chemisorption)	*Nonspecific sorption only (ion exchange)*	*Both specific and nonspecific sorption*
Anion	OH^- PO_4^{3-}, AsO_4^{3-}, SeO_3^{2-}, and F^-	CO_3^{2-}, Cl^-, Br^-, I^-, NO_3^-, and $B(OH)^{4-}$	MoO_4^{2-}, SeO_4^{2-}, SO_4^{2-}, and CrO_4^{2-}
Cation	Ni^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Mn^{2+}, and Ag^+	Ca^{2+}, Mg^{2+}, Li^+, Na^+, Ba^{2+}, and NH_4^+	K^+, Cd^{2+}, and Hg^{2+}

Note: Ions listed under specific sorption can also bind by nonspecific sorption, but those listed under nonspecific sorption never bind by specific sorption. Those listed under 'both' have only a weak ability to bind by specific sorption mechanisms.

charges held onto the soil by the ion-exchange mechanism is the anion-exchange capacity (AEC). In general, the composition of nutrients on the ion-exchange sites is proportional to the solution composition of ions. For example, if the soil CEC contains 20% Al^{3+}, 40% Ca^{2+}, 10% K^+, 10% Na^+, 10% H^+, and 10% Mg^{2+}, then the solution will contain those ions in a similar ratio.

Ligand-exchange and chemisorption (specific sorption) reactions

Ligand exchange and chemisorption are the names given to the 'specific' sorption reactions for anions and cations, respectively. Specific sorption differs from ion exchange (nonspecific sorption) in that the reaction results in a strong covalent bond, because the ion is bound directly to the surface with no water molecule in between. As a result, nutrients held by specific sorption are bound somewhat irreversibly, that is, a portion of nutrients that are sorbed by this mechanism will not completely desorb (i.e., hysteresis). In addition, specific sorption occurs dominantly on edge terminal hydroxide groups among variable-charge minerals as opposed to permanent-charge minerals, which mostly retain nutrients by weak ion-exchange reactions. Another difference between ion exchange is that specific sorption reactions can occur on positive, negative, or neutral surfaces; this is due to the fact that the bound nutrient actually becomes somewhat part of the surface (known as the Stern layer) of the variable-charge mineral. Thus, there is a general trend that specific sorption of anions can increase the negative charge (i.e., increase CEC) and sorption of cations can increase positive charge (i.e., increase AEC).

Soil pH has an impact on specific sorption due to the increased competition with H^+ at low pH and OH^- with increasing pH. Particularly, specific sorption of cations (i.e., chemisorption) decreases with a decrease in pH as the cation must compete with protons that have a strong affinity for the surface of variable-charge minerals. Likewise, specific sorption of anions (i.e., ligand exchange) is lessened with increasing pH due to competition with OH^-, as OH^- is itself a ligand. Cations that can potentially bind strongly via chemisorption are those that easily hydrolyze, which are mostly transition metals, such as the micronutrients Zn^{2+} and Cu^{2+}. In general, 'base cation' nutrients, which consist of the alkali and alkali earth metal nutrients (Ca^{2+}, Mg^{2+}, and K^+), bind only by ion-exchange reactions, although there are several exceptions discussed%% later. Anions that can potentially bind by ligand-exchange to variable-charge sites are typically oxyanions, such as phosphate and molybdenate. Anions that can bind strongly by ligand exchange (such as phosphate) will outcompete anions that can only bind by the weak ion-exchange mechanism (such as nitrate) and anions that can bind by ligand exchange with less strength (such as sulfate). Table 3 shows which ions are capable of binding by specific sorption.

Precipitation and dissolution

Precipitation and dissolution make up the third category of reaction mechanism that enables soils to both bind and release ions into solution, making them available for plant uptake or mobile for water transport. Precipitation theory states that as the concentration of an ion in solution increases, precipitation of a new solid phase does not occur until the solubility product of that phase has been exceeded.

Generic reaction showing the precipitation of a reaction product from an anion and a cation (eqn [3]).

$$A_n^- + C_{at}^+ \leftrightarrow P_r;\ k = X \qquad [3]$$

Equation [3] provides a general reaction where an anion (A_n^-) and cation (C_{at}^+) react with each other to form a solid precipitant or mineral (P_r). The ions on the left side of the reaction are the reactants, and the solid mineral on the right side is the product. There is equilibrium between the reactants and products that is quantified by the reaction constant k, which is unique to each mineral. This concept of equilibrium is the same as was described for specific and nonspecific sorption except that the product is a solid mineral. Le Chatelier's principle also applies to precipitation reactions and their reverse reaction, dissolution of the mineral back into the soil solution. Depending on the ion concentrations in solution and the potential presence of a solid mineral, the ions may react with each other to form a solid mineral, thereby leaving the solution where they cannot be taken up by a plant, or conversely the solid may dissolve to resupply the solution with the ions where they can be taken up by a plant.

Many plant nutrients are subject to precipitation and dissolution reactions that can impact nutrient availability. Those most affected ones include P, Ca, Mg, and trace metals. Because most precipitation and dissolution reactions involve OH^- or H^+, nutrient availability of such ions tend to be highly pH dependent. The impact of pH on nutrient availability is discussed in the Section pH and Soil Fertility.

Soil Type

Soil type plays a profound role in soil fertility because mineralogy partly dictates soil type and mineralogy controls the capacity and strength in which nutrients are retained. For this

discussion, the term 'soil type' will be relegated to the most broad soil taxonomic category, soil order (based on US Department of Agriculture soil taxonomic classification system).

Because soil orders are classified partly due to their mineralogy, and as mineralogy partly dictates fertility, knowledge of the soil order can provide useful information regarding fertility. As discussed in the Section Permanent-charge versus variable-charge minerals, 2:1 minerals that possess accessible permanent negative charge have the highest CEC among soil minerals and therefore the greatest capacity to retain base cations, such as K^+, Ca^{2+}, Mg^{2+}, and NH_4^+. Typically, these include the soil clay minerals montmorillonite and vermiculite. However, these minerals possess very little AEC as they have little to no variable charge. Because variable-charge minerals have the ability to strongly sorb nutrients by ligand exchange and chemisorption, soils dominated with variable-charge minerals tend to 'fix' ions (i.e., prevent them from entering solution) that are highly susceptible to such reactions (Table 3) and are considered infertile. Another reason variable-charge minerals are typically considered infertile is because they generally have a low CEC. However, soils dominated with variable-charge minerals have the ability to prevent excessive runoff and leaching losses of P and trace metals, thereby preventing a potentially negative environmental impact in cases when excessive nutrients are applied.

As a general rule, 'younger' soils are more fertile than 'older' ones as the former is dominated by permanently charged 2:1 minerals, whereas the latter is dominated with variable-charge 1:1 and metal oxide or hydroxide minerals. In this context, 'younger' and 'older' refers to soil development as impacted by the five soil-forming factors (parent material, climate, organisms, topography, and time). The five soil-forming factors generally transform minerals from primary minerals to high-layer charge 2:1 minerals (i.e., mica and illite), lower-layer charge 2:1 minerals (i.e., montmorillonite and vermiculite), 1:1 minerals, and finally metal hydroxides.

Some of the least developed soil orders, which include Entisols and Inceptisols, do not necessarily fit this general rule because the mineralogy of these soil orders are mostly a function of their parent geologic material. Aridisols are characterized by a high level of primary minerals, mainly sulfates and carbonates. These soils develop in areas of low rainfall and often possess naturally high amounts of K, Ca, Mg, and S but a low CEC and AEC due to the lack of more developed minerals. One of the least developed and most fertile soil orders, Andisols, are derived from relatively recently deposited volcanic materials and are, therefore, rich in amorphous 2:1 minerals with high CEC. Similarly, Vertisols are dominated by montmorillonite and therefore are considered to be highly fertile. As soils weather and 2:1 minerals begin to give way to 1:1 minerals, Mollisols and Alfisols are formed. The former is distinguished by higher levels of organic carbon, making it more fertile than Alfisols, but both soil orders are characterized as having 'high' base cation saturation ($>35\%$). With continued development, Ultisols are formed, which contain less 2:1 minerals and more 1:1 and metal oxides and hydroxides, which results in a lower base cation saturation ($<35\%$) and therefore a decreased CEC. Still, the most developed soil order is the Oxisol, which has very little CEC and is dominated by 1:1 minerals and metals oxides and hydroxides.

pH and Soil Fertility

Soil pH is considered the 'master variable' in soil fertility for several reasons. Soil pH often has a large impact on (1) precipitation and dissolution of primary minerals, (2) the degree of CEC and AEC on variable-charge minerals, (3) the degree of ion-exchange, ligand-exchange, and chemisorption reactions, (4) microbial activity that impacts nutrient cycling, and (5) the solubility of Al. The general change in nutrient availability with changes in pH is shown in Figure 4. One of the most important aspects of the impact of pH on soil fertility is percent base cation saturation of the CEC. Percent base saturation is quantified as the amount of exchangeable base cations divided by the soil CEC and multiplied by 100%. Soils with low percent base saturation are considered infertile, whereas those with high saturation are fertile. Soils with low-base saturation are dominated by H^+ and Al^{3+}, contributing to acidity and Al^{3+} toxicity in plants. Indeed, it is the increased solution concentrations of Al^{3+} and Mn^{4+} that are often most detrimental to plant growth under acidic pH conditions. The influence of soil pH on nutrient availability to plants varies with nutrient and soil mineralogy. Details on the interaction between soil pH and nutrient availability is covered in more detail in the following Section Nutrient Cycling and Plant Nutritional Roles of Essential Elements.

pH management

Most weathered soils in humid regions act as weak acid systems where the total acidity is much greater than the active acidity and therefore the potential acidity is great. Soil systems become more acidic as H^+ ions are released into solution through the dissociation or ionization of acids. Many soil processes can contribute to soil acidity, including the dissolution of CO_2 gas (originating from organic matter decomposition or soil microbial respiration) into water to form carbonic acid (H_2CO_3), clay structure mutations, hydrolysis of Al, acid rain, leaching or weathering of soils, plant uptake of base cations, and oxidation of S. One of the principle farming practices that contributes to soil acidity is the use of ammoniacal fertilizers, such as ammonium nitrate, which produces acidity as ammonium is oxidized during the nitrification process. As a result of the various natural processes and anthropogenic activities that contribute to soil acidity, many soils require the addition of acid-neutralizing materials, generally called 'liming materials,' to increase the pH and optimize plant performance. Liming materials contain an anion that removes H^+ from solution and precipitates Al^{3+} into a solid mineral, thereby reducing acidity. Most liming materials are oxides, hydroxides, carbonates, or silicates of Ca or Mg, or both. The standard liming material is Ca carbonate ($CaCO_3$), found as the mineral calcite, or some mixture of Ca and Mg carbonate ($CaMg(CO_3)_2$; dolomite). Other common materials include burned lime (CaO and MgO), hydrated lime ($Ca(OH)_2$ and $Mg(OH)_2$), and certain byproducts of manufacturing processes. Many manures or biosolids contain appreciable amounts of carbonates and can raise soil pH. The neutralizing power of a potential liming material is expressed by its Ca carbonate equivalent (CCE), which is a normalization of neutralizing power relative to pure calcium carbonate. The higher the CCE, the more potent the liming material is on a

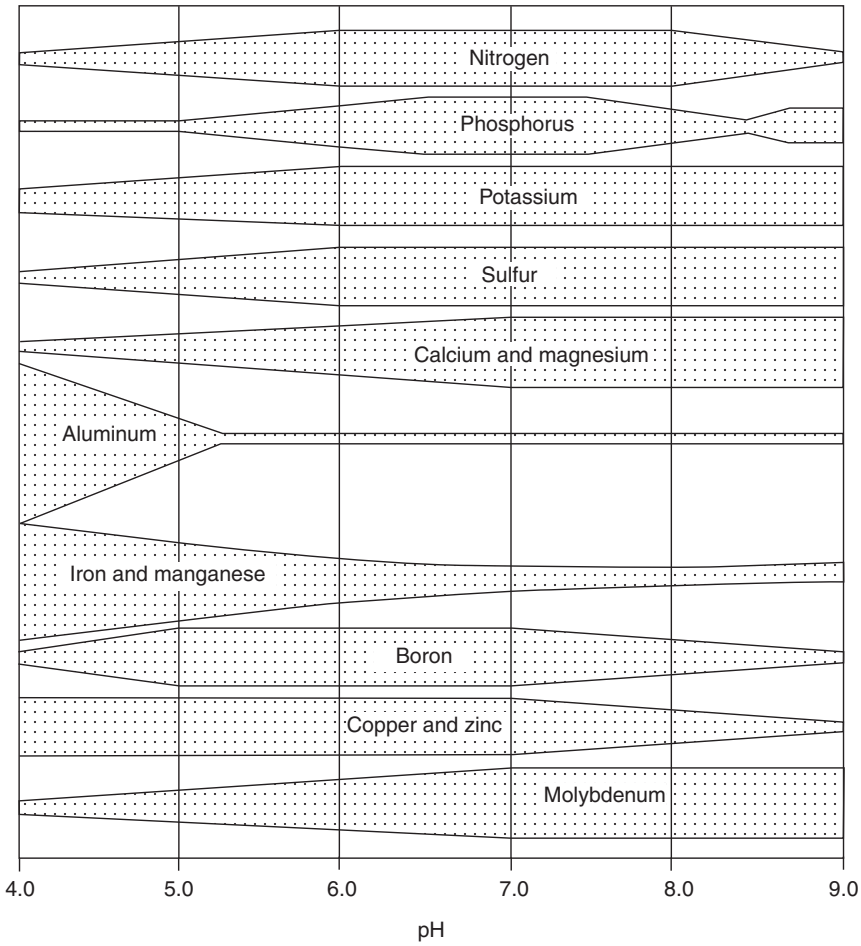

Figure 4 The relative availability of the essential plant nutrients varies with pH. In this classic figure, the width of the bar indicates relative nutrient availability; as bar width increases, the nutrient availability increases as well. Adapted from Truog, E., 1947. Soil reaction influence on availability of plant nutrients. Soil Science Society of American Journal 11, 305–308.

mass basis. Equation [4] presents the generalized lime reaction for calcium carbonate as a two-step process.

Generalized lime reaction using calcium carbonate as the liming material (eqn [4]).

$$\begin{aligned}&\text{Step 1: } CaCO_3 + H_2O \rightarrow Ca^{2+} + HCO_3^- + OH^-\\&\text{Step 2: } OH^- + H^+ \rightarrow H_2O\end{aligned} \quad [4]$$

Lime requirement is defined as the quantity of limestone or other basic material required to raise the pH of the soil to the desired value that is needed on the basis of the intended use of the soil. The amount of liming material applied must be sufficient to not only neutralize the H^+ and Al^{3+} in solution (active acidity) but also neutralize much of the exchangeable and nonexchangeable acidity (or potential acidity). The exchangeable and nonexchangeable acidity is the H^+ and Al^{3+} associated with the solid phase, and the two are distinguished from each other through an operational definition: exchangeable acidity is extractable with a 1 M KCl solution. It is this solid phase H^+ and Al^{3+} bound to soil organic matter and clay minerals that buffers the soil solution. Thus, as the solution acidity is neutralized, the exchangeable acidity pool resupplies the solution with H^+ and Al^{3+}, and then the nonexchangeable pool resupplies the exchangeable pool. Soils that can retain more H^+ and Al^{3+} are more buffered and typically have higher amounts of clay and organic matter. These well-buffered soils require a greater amount of liming material to neutralize acidity, but the soils also remain near neutral for a greater period of time. Conversely, sandy soils with low organic matter require little liming material to neutralize soil acidity but require more frequent liming. Overall, factors that affect lime requirement include initial soil pH, desired soil pH, and soil buffer capacity. Although there are many methods of estimating lime requirement, most soil testing labs utilize some type of calibrated buffer solution, such as the Adams–Evans, Shoemaker–McLean–Pratt (SMP), or Mehlich buffers.

There are some soils that have excessively basic soil pH, and in some instances it is economically feasible to acidify them. This is especially true of high-pH soils that display micronutrient deficiencies; a decrease in pH often alleviates the deficiency. Basic soils are usually treated with elemental sulfur, Fe or Al sulfate, ammonium-containing fertilizers, or sulfuric acid. Although elemental sulfur is often the most economical treatment, it requires microbial activity to be reduced to sulfate, and therefore time, before the pH is decreased. Fe or Al

sulfates or NH_4SO_4 do not decrease pH due to the sulfate, but through the hydrolysis of Fe^{3+} and Al^{3+} that is released from these highly soluble minerals or nitrification of NH_4. Sulfuric acid can be injected into irrigation systems and works very rapidly but requires special handling due to its caustic nature. A general acid-producing reaction from application of Al sulfate is shown in eqn [5], which results in the precipitation of an amorphous Al hydroxide mineral.

Acidifying reaction resulting from the application of aluminum sulfate (eqn [5]).

$$Al_2(SO_4)_3 + 6H_2O \leftrightarrow 2Al(OH)_3 + 6H^+ + 3SO_4^{2-} \quad [5]$$

Nutrient Cycling and Plant Nutritional Roles of Essential Elements

As described in the Section Soil Characteristics Contributing to Nutrient Supply, the macro- and micronutrients are present in varying degrees in soil and their availability is dependent on soil mineralogy and soil chemical and physical characteristics. Understanding how the essential elements cycle in the soil and are utilized by plants is critical to understanding how to manage them to optimize plant performance. Table 2 provides a brief overview of each of the essential elements and their functions in plants. The following sections briefly describe management of each of the essential elements in regard to their plant–soil cycle. In essence, applied soil fertility and plant nutrition revolves around the management of the plant–soil nutrient cycle to provide these nutrients in adequate amounts for optimum plant performance.

Primary Macronutrients

Nitrogen

Nitrogen is present in plant tissue at the highest relative abundance of the essential mineral nutrients that comprise from 1% to 5% of plant dry matter. Plants use N to form amino acids, which are subsequently incorporated into proteins and nucleic acids (DNA and RNA). Nitrogen is also an integral component of chlorophyll, the light-absorbing pigment needed for photosynthesis. Because of the high N requirement of most crops and its mobility in the environment, it is also commonly the most limiting nutrient in both managed and natural ecosystems. As a result, N is typically the nutrient that receives the most attention.

Nitrogen behavior is arguably more dynamic than any of the other essential mineral elements (Figure 5). The ultimate source of most plant-available N is N_2, which comprises 78% of the earth's atmosphere. However, most plants can only utilize NO_3^- or NH_4^+ from the soil solution, referred to as plant-available forms. Conversion of N_2 to plant-available N is called fixation and is a very energy-intensive process as it requires breaking the strong triple bonds of the thermodynamically stable N_2 molecule. Legumes have symbiotic relationships with rhizobia bacteria that can fix N_2 from the soil atmosphere. Biological N_2 fixation (BNF) is catalyzed in the presence of the nitrogenase enzyme produced by these bacteria (eqn [6]). For nonleguminous plants, N sources include N fixed from atmospheric N_2 introduced to the soil system by nonsymbiotic soil microorganisms capable of BNF, atmospheric deposition of N oxides formed either through electrical discharges or through high temperature combustion, and the application of industrially fixed N fertilizers. Natural processes (e.g., lightning and volcanic activity) as well as human activities (e.g., operation of internal combustion engines and industrial fixation of N to make inorganic fertilizer) convert N_2 to NH_3 through thermal fixation, as described in eqn [7].

BNF (eqn [6]).

$$N_2 + 8H^+ + 8e^- + 16ATP \xrightarrow{\text{nitrogenase}} 2NH_3 + H_2 + 16ADP + 16P_i \quad [6]$$

Thermal nitrogen fixation (eqn [7]).

$$N_2 + 3H_2 \rightarrow 2NH_3 \quad [7]$$

The soil N cycle is very complex because it varies greatly, both in space and time, due to the influence of biotic and abiotic transformations. The total N content of the surface 20 cm of mineral soils is generally within the range of 0.05 to 0.5%. Soil N can be generally classified as organic or inorganic. Soil N resides in soil solution, soil organic matter, clay mineral surfaces (typically residing in the interlayer of 2:1 clays), or in the soil atmosphere (although this is typically transitive in nature). Forms of inorganic N include exchangeable NH_4^+, fixed or nonexchangeable NH_4^+, NH_3, NO_3^-, N_2, N_2O, and N oxides. Inorganic N generally represents less than 5% of the total soil N. Organic N forms include amino acids or proteins, amino sugars, and a large pool of unidentified compounds. Organic N is a component of soil organic matter, including microbial biomass and organic residues from plants and animals. The major N transformations that dominate the soil N cycle include N_2 fixation, nitrification, mineralization, biological immobilization, chemical immobilization, deprotonation of NH_4 to NH_3, and denitrification.

The interrelationship and transformation of N between the inorganic and organic pools is the most central aspect of the N cycle and dominates the management of N for crop production. Nitrogen mineralization is the conversion of organic N into inorganic forms, both NH_4^+ and NO_3^-, whereas N immobilization refers to the transformation of inorganic N into organic forms. Typically, N immobilization is used to refer to biological processes, such as assimilation by microorganisms; however, NH_4^+ can also be immobilized by direct adsorption and incorporation into soil organic matter. Furthermore, some microorganisms can directly assimilate NO_3^-; however, this is typically explicitly referred to as NO_3^- assimilation. Mineralization typically involves three steps and results in the production of both NH_4 and NO_3^-. In the first step, aminization, heterotrophic soil organisms decompose complex proteins into simple amines and amino acids (R–NH_2). During the second step, ammonification, the amines and amino acids are further decomposed by other heterotrophs, releasing NH_4 (eqn [8]). Finally, ammonium can be converted to nitrate through nitrification (eqns [9] and [10]). Nitrification itself is a two-step process where obligate autotrophic *Nitrosomonas* bacteria first oxidize NH_4^+ to NO_2^- (eqn [9]) then the obligate autotrophic *Nitrobacter* oxidize NO_2^- to NO_3^- (eqn [10]).

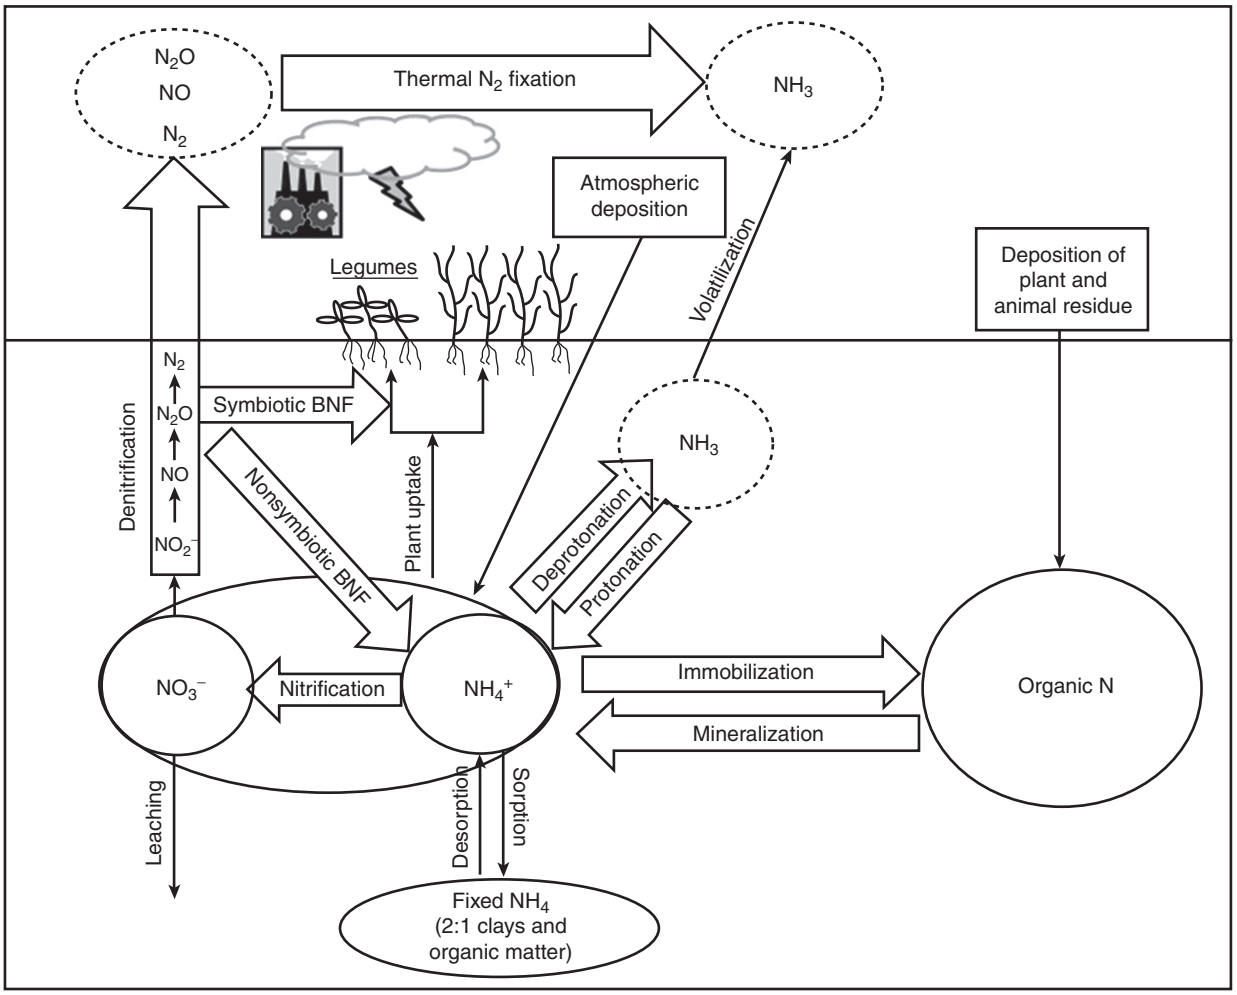

Figure 5 The soil nitrogen cycle, with major transformations (block arrows), pools (ovals), and movement into, out of, and through the soil system identified.

Ammonification (eqn [8]).

$$R-NH_2 + H_2O \rightarrow NH_3 + R-OH + \text{energy} \quad [8]$$

Oxidation of ammonium by *Nitrosomonas* (eqn [9]).

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 2H_2O + 4H^+ \quad [9]$$

Oxidation of nitrite by *Nitrobacter* (eqn [10]).

$$2NO_2^- + O_2 \rightarrow 2NO_3^- \quad [10]$$

Nitrogen transport and transformation processes are inextricably linked within the soil system because the form of N present is influenced by both, and they determine storage or loss patterns. The loss of N from the soil system has significant implications for both crop production and environmental quality. The vast majority of industrially fixed N applied as fertilizer is as NH_4^+ or forms that release NH_4^+ when applied, such as urea ($CO(NH_2)_2$). Once in the soil, NH_4^+ can be rapidly deprotonated to form NH_3, particularly in neutral or alkaline soils, and lost to the atmosphere through volatilization (eqn [11]). Urea accounts for approximately half of the ammoniacal fertilizer applied. Urea is rapidly converted to NH_4^+ through urea hydrolysis, an enzymatic reaction where urea and water react in the presence of urease to form NH_4^+ and HCO_3^-. When urea fertilizers are surface applied or incorporated into low CEC soils (particularly if incorporated to shallow depths), this reaction often continues to form NH_3 and CO_2. The two ammoniacal forms, NH_4^+ and NH_3, are in equilibrium in the soil and the partitioning between the two is highly dependent on pH.

The deprotonation of ammonium produces ammonia gas that can volatilize to the atmosphere (eqn [11]).

$$NH_4^+ \leftrightarrow NH_3 + H^+;\ pK_a = 9.25 \quad [11]$$

Retention of N in the soil as NH_4^+ is important to crop production as this form provides favorable energy balance to crops in regard to N utilization and because NH_4^+ is held by the soil CEC, it is less susceptible to loss. Nitrification is an important process in the soil N cycle because it is assumed that in most systems the majority of N is lost through NO_3^-

leaching. Nitrate is a poorly held anion, easily transported out of the soil system through leaching or runoff.

Biological denitrification is the reduction of nitrogen oxides under anaerobic conditions. It can be a major N loss pathway from agricultural soils, particularly when they are periodically inundated with water. It is important to the global N cycle because it is the principle pathway by which inorganic N in soil or surface water returns to the atmospheric N pool as N_2, N_2O, or NO, the latter two contributing to greenhouse gases and ozone depletion, respectively.

Nitrogen fertilizer efficiency or N use efficiency are terms generally used to quantify how much of the applied N fertilizer makes it into the target plant or the harvested portion of the crop. There are many ways to calculate N use efficiency (see Section Relevant Websites – Oklahoma State University's NUE website). Nitrogen's mobility in the environment, and specifically the plant–soil system, contributes to low global N use efficiency. For example, Raun and Johnson (1999) estimated N use efficiency in global cereal production at approximately 33% in 1996. One of the most critical steps to increase N use efficiency is determining the correct amount of N required to optimize crop performance. Nitrogen's mobility makes predicting the correct amount of N needed for optimum plant performance very difficult. Most recommendation systems rely on a mass balance approach, as detailed by Stanford (1973). Fundamentally, the mass balance approach accounts for the N requirement of the crop, the amount of N supplied by the soil through mineralization of organic N or residual mineral N present in soil, externally supplied N (e.g., through precipitation), and N lost through various pathways. The difference between N supplied and N required is then determined to be the amount needed through fertilization. Through repeated plot trials, agronomists have developed region-specific, empirical relationships between applied N rate and yield based on Stanford's equation. Some recommendation systems also included economic factors and may be grouped by soil type, rather than relying on estimated yield alone; however, these recommendations are still based on empirical results from N rate response trials (Sawyer *et al.*, 2006). Regardless of how recommendations are generated, the objective is to maximize return on N fertilizer investment by optimize plant performance and minimizing residual reactive N that can be lost to the environment. Beyond determining the optimum rate, increasing N fertilizer use efficiency is also highly dependent on timing of N fertilizer application. Because N is so mobile in the environment, applied N that is not immediately taken up by plants is at constant risk for transport out of the soil system. One way to mitigate this is to time N applications to match the temporal plant uptake patterns as closely as possible. This can be accomplished by splitting the total amount of N fertilizer thought to be required among multiple applications in an attempt to match the timing of plant uptake. Another method to increase N fertilizer efficiency is the use of 'slow-release' fertilizers designed to release N slowly over time, in the hope that plants then take up the N as it is released, minimizing the time that mobile forms of N are in the soil system and at risk for loss to the environment. Similarly, certain formulations of N or chemical treatments of N fertilizers attempt to disrupt N transformations to limit its mobility in the environment. Nitrification and urease inhibitors fall into this category. Finally, N fertilizer efficiency can be manipulated by where the fertilizer is placed. For example, as described above, urea fertilizer can rapidly hydrolyze to form NH_4, which can deprotonate and then volatilize, being lost to the atmosphere as NH_3. However, simply incorporating urea fertilizer below the soil surface can significantly reduce NH_3 gaseous losses. Overall, soil fertility managers must focus on rate, timing, form, and placement of N fertilizer in order to maximize the efficiency of applied fertilizers.

Phosphorus

Phosphorus is essential for all forms of life on the earth. It is typically less abundant in the soil than N or K, with total P concentrations in soil ranging from 50 to 1500 mg kg^{-1}. Likewise, typical total P concentrations in plant tissue are approximately an order of magnitude less than N or K concentrations, averaging 0.2% (dry weight basis; **Table 2**). Phosphorus is involved in almost every metabolic and reproductive process in plants and is most often associated with vigorous growth, development of reproductive parts, and energy transfer. Phosphorus is important in the storage and transfer of energy in plants, as a basic building block of ADP and ATP. Sugar phosphates are an essential structural component of DNA and RNA, which contain the genetic coding responsible for plant growth, development, and metabolism. Phospholipids and phosphoproteins are important structural components of membrane chemistry.

Phosphorus occurs in many forms in the soil. It resides in and moves between three major pools: organic P, inorganic P, and soil solution P as part of the soil P cycle (**Figure 6**). Plants can absorb phosphate from the soil solution as either dihydrogen phosphate ($H_2PO_4^-$) or hydrogen phosphate (HPO_4^{2-}), depending on soil pH. To a more limited extent, plants can also absorb low molecular weight, soluble organic compounds, such as phytin and nucleic acid, from the soil solution; however, these dissolved organic P compounds are considered a negligible source of P for higher order plants. Inorganic P can be found in forms that are readily available, slowly available, or very stable. The degradation of organic compounds to release phosphate or soluble organic P to solution is referred to as mineralization. Solution P can be fixed through adsorption to clay and mineral surfaces or precipitation of secondary minerals. Phosphate can be released to the soil solution from secondary minerals and primary minerals through dissolution and from clay and mineral surfaces through desorption. Easily mineralized organic P, readily desorbable inorganic P, and soluble P are all forms of P readily available for plant uptake and are often referred to as labile P. Generally, organic P that is more recalcitrant and primary or secondary mineral P are considered nonlabile. The quantity–intensity relationship described in the Soil Mineralogy Section and **Figure 3** depicts the relationship between labile P and solution P. As plants remove phosphate from soil solution, labile P replenishes the solution pool. This relationship is highly dependent on soil mineralogy and pH.

Soil P differs from N and K in that it can bind somewhat irreversibly to variable-charge minerals by ligand-exchange (specific sorption) mechanisms. For example, as pH decreases below 6 (**Figure 4**), phosphate has less competition with OH^-

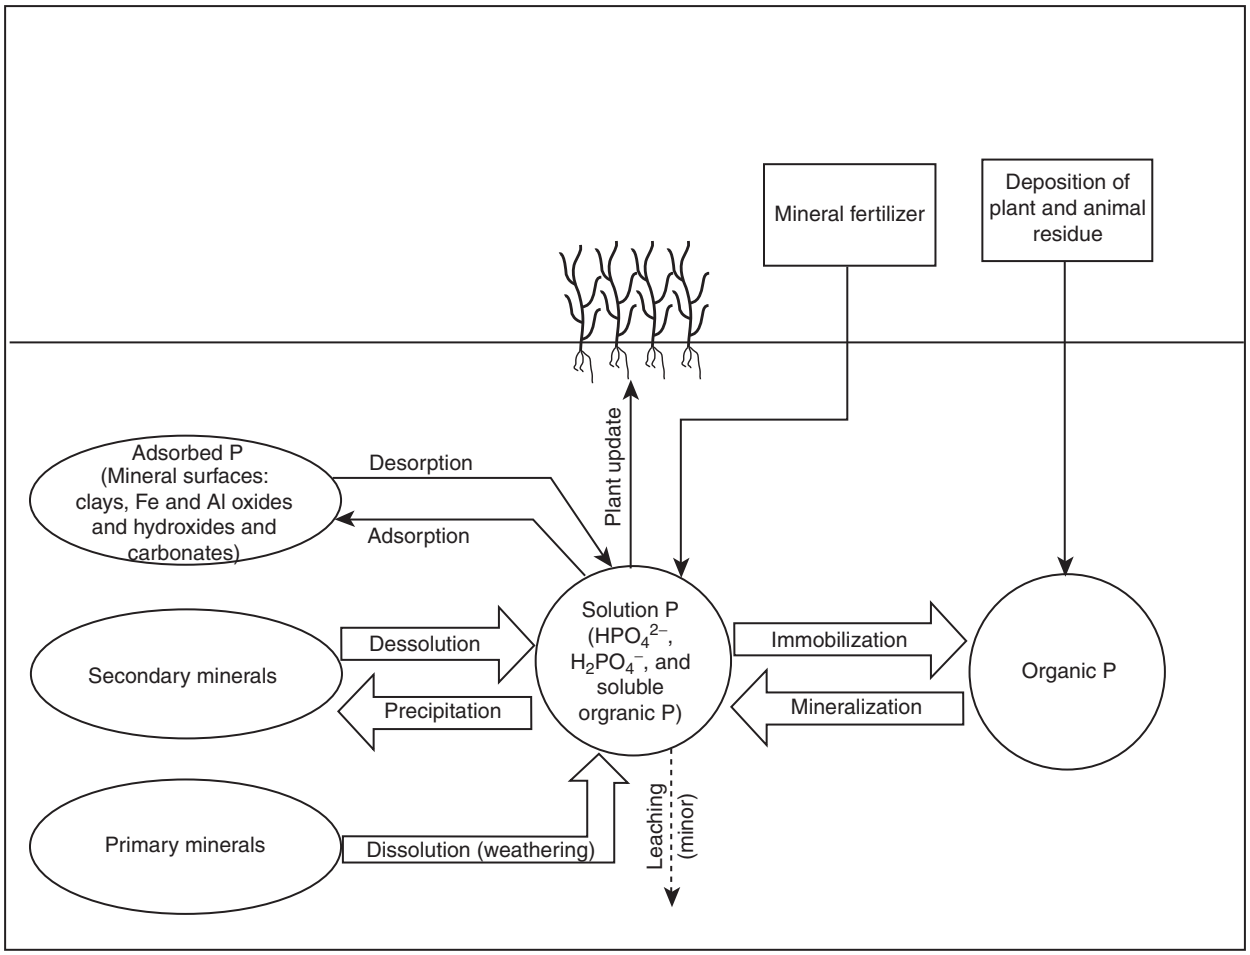

Figure 6 The soil phosphorus cycle, with major transformations (block arrows), pools (ovals), and movement into, out of, and through the soil system identified.

and the mineral surfaces become more positively charged, which together results in a strong ligand-exchange reaction on the surface. The problem is that the phosphate is often held so strongly that it cannot desorb back into solution until the pH appreciably increases. This is most common in Ultisols and Oxisols because they are rich in Fe and Al oxides and hydroxides. Another way in which P availability differs from N and K is that P is extremely susceptible to precipitation reactions with Al, Fe, Mg, and Ca. At pH below 6, P begins to precipitate as a solid Al or Fe phosphate mineral, which is also a common problem in Ultisols and Oxisols. In addition, as pH increases above 7, P begins to precipitate as a solid Mg and Ca phosphate until the pH reaches approximately 8.2 (**Figure 4**). Because of the impact of pH on ligand-exchange and precipitation reactions, optimum P availability is assumed to be approximately pH 6.5.

Organic P accounts for less than 50% of P found in surface soils. Plant material and organic wastes supply organic P to soils. These organic materials are typically deposited on the surface, and as P is not easily transported downward through soil, the largest portion of the organic P pool is contained in the topsoil. Most of the soil organic P occurs as stable, organic compounds not readily available for plant uptake. Nonetheless, mineralization of organic P through microbial activity can provide labile organic P for crop use, albeit at a very slow rate.

Inorganic P in acidic soils not taken up by plants can be fixed or sorbed by iron (Fe) and aluminum (Al) oxides, organic matter, and clay minerals or precipitate as Fe and Al minerals. In alkaline soils, calcium (Ca) phosphates rather than Fe or Al phosphates are the dominant minerals controlling P fixation (Lookman *et al.*, 1996; Van der Zee and van Riemsdijk, 1988). Most inorganic forms of P in the soil are sparingly soluble. Desorption of P from metal oxides, clays, and organic matter or dissolution of Ca, Fe, and Al minerals replenishes soluble P removed by plant uptake or runoff.

Mineralization of organic P and dissolution (or weathering) of stable P minerals are natural processes that provide labile P to crops. However, in soils that have low to medium soil test P values, these processes typically proceed too slowly to supply sufficient available P for plant growth. Therefore, it is often necessary to provide P to crops through fertilization. Organic and inorganic fertilizers are most commonly used to build soil P fertility to the optimum concentrations that can replenish soil solution P for production of crops.

Organic fertilizers, such as manures and biosolids, provide essential nutrients, such as P and N, and add organic matter,

which can improve soil fertility. Best management practices, such as immediate incorporation of manure after application, can reduce the potential for environmental impacts resulting from manure use. When properly managed, manures and other organic P sources can provide nutrients with no more environmental consequences than well-managed commercial fertilizers. However, use of manures as fertilizers can complicate nutrient management because of the unpredictability of organic nutrient mineralization and the fact that many constituents are present inorganic fertilizers at varying and often unknown concentrations.

Inorganic fertilizers can be easier to manage than organic fertilizers. The primary advantages of inorganic fertilizer over organic fertilizer, from an environmental standpoint, are: (1) that the application of a specific nutrient is independent of other nutrients; (2) the P content of inorganic fertilizers is known and uniform, permitting the user to apply the desired amount of P accurately; (3) inorganic fertilizers are homogeneous in composition, produced in granular, pelletized, or liquid forms, allowing more even distribution; and (4) dissolution of inorganic fertilizers is more predictable than organic fertilizers, so that timing and rate of application can be accurately determined. Good management practices, such as band application and fertilizer incorporation, can further enhance fertilizer efficiency. Band application of fertilizer increases the concentration of nutrients near the root zone, improving the plant's ability to utilize the nutrients. Furthermore, incorporating or injecting fertilizers reduces fertilizer loss in runoff and erosion (Baker and Laflen, 1982).

Potassium

Potassium is adsorbed by plants more and is present in plant tissue at higher concentrations than any other essential nutrient except for N (Table 2). It is responsible for water relations and charge balance in plant cells and is highly mobile within the plant. The primary nutrients, N, P, and K, are typically lacking in the soil due to the natural geologic material. However, soils rich in micas (biotite and muscovite), illite, or vermiculite tend to contain naturally adequate levels of K. As the K is bound up as part of the minerals, it requires the influence of the five soil-forming factors to weather the mineral and release K^+ to solution for plants. Older or highly weathered soils or soils in areas with high rainfall are more prone to exhibiting K deficiency due to leaching of K^+. Potassium is one of the base cation nutrients (along with Ca^{2+} and Mg^{2+}) that typically only bind by ion exchange reactions discussed in the Section Ion-exchange reactions (nonspecific sorption). When K^+ is not bound tightly by the aforementioned minerals or located in solution, it can bind to the soil CEC through nonspecific sorption where it can be easily displaced into solution by another cation. Thus, it is found that K^+ availability decreases when the soil pH decreases below 6 because the soil CEC resulting from variable-charge minerals decreases. Another reason for the decrease in K^+ availability in acid soils is because of increased competition from Al^{3+} and H^+ ions. Specifically, Al^{3+} concentrations or, more specifically activity, increase in acidic soils due to the dissolution of Al hydroxide minerals (eqn [12]).

Al hydroxide minerals can dissolve, releasing Al^{3+} to solution, decreasing K^+ activity, which allows K^+ to leach out of the root zone (eqn [12]).

$$Al(OH)_3 + 3H^+ \leftrightarrow Al^{3+} + 3H_2O \quad [12]$$

This reaction occurs for a variety of Al oxide and hydroxide minerals, and the net result is that soil Al tends to buffer the pH at approximately 5.5. The increased concentration of Al^{3+} causes the activity of Al^{3+} to increase and the activity of K^+ to decrease. Thus, the soil CEC and solution becomes dominated with Al^{3+} and K^+ is then able to leach out of the soil along with other base cations.

Soil K resides in five primary pools: organic matter, primary minerals (feldspars and micas), nonexchangeable K^+ (retained in the inner layer of 2:1 minerals), exchangeable K^+ (sorbed on the surface of 2:1 minerals), and soil solution K^+ that is available for plant uptake. Potassium in soil organic matter comes from the deposition of plant and animal materials, which can be quite high in K content. Unlike other nutrients, K is not a structural component of plant tissue; rather it exists as an ion in solution or bound to charges on tissue surfaces. Therefore, decomposition of organic matter can rapidly and directly contribute K^+ to the soil solution pool. The soil solution pool can also be replenished rapidly through desorption of K^+ from 2:1 clay mineral surfaces. Because exchangeable K^+ is in equilibrium with the solution pool, it can be replenished through adsorption from the solution pool. By contrast, nonexchangeable K+ held tightly in the inner layer of 2:1 minerals equilibrates very slowly, releasing K^+ to the exchangeable and solution pools over long periods of time and at not a fast enough rate to supply crop needs. The nonexchangeable pool primarily originates from the weathering of soil minerals or the fixation of exchangeable K^+. Potassium can be lost from the soil system through leaching or plant uptake, adsorbed as K^+.

Secondary Macronutrients

Calcium and magnesium

Calcium and Mg are often found in soil minerals originating from geologic parent material, and therefore their plant availability is usually a function of the solubility of those minerals. Plants require approximately the same amount of Mg as they do P, with Ca requirement approximately double of that (Table 2). Soils rich in Ca- and Mg-containing minerals are often found in arid and semiarid areas or are younger soils formed from recently deposited parent material. The source of Ca and Mg are typically carbonate minerals that dissolve with decreases in pH that occur with normal agricultural activities and rainfall. As a result, it is typically not required to fertilize for Ca and Mg in these soils. However, assuming that Ca and Mg are present in the soil, Figure 4 shows that their availability decreases as the pH drops below 6. This is because Ca and Mg are base cations that are held onto the CEC by ion exchange reactions if they are not precipitated as a solid mineral. Therefore, acid pH allows Al^{3+} to dominate the CEC and solution, thereby decreasing Ca and Mg activity and allowing them to potentially leach. Course-textured soils in humid areas are generally very low in Ca; however, the application of agricultural lime to manage soil acidity in these soils typically provides sufficient Ca and Mg for optimum

plant growth. As soil pH increases above pH 8, Ca and Mg availability decreases as a result of precipitation with carbonates.

The soil cycles for Ca and Mg are very similar to the soil K cycle. Plants adsorb Ca^{2+} and Mg^{2+} from the soil solution, which is in equilibrium with mineral forms of the two elements and exchangeable forms sorbed to clay mineral surfaces. The processes of desorption and adsorption maintain the equilibrium between the soil solution and exchangeable Ca^{2+} and Mg^{2+}. Both Ca^{2+} and Mg^{2+} in solution can precipitate to form secondary minerals, which can dissolve to replace solution Ca or Mg that has leached out or been removed by plant uptake. Organic residues also contain Mg and Ca that can feed the soil solution pool, but the soil cycle is by far dominated by inorganic cycling.

Plants obtain Ca^{2+} and Mg^{2+} from the soil solution through mass flow and root interception. Calcium is a principle component of cell wall structures and important to cell wall permeability. Because of its importance to cell structure, Ca^{2+} is essential for development of terminal buds and shoots and the apical tips of roots and is also involved in the translocation of nutrients and carbohydrates produced through photosynthesis (Tables 1 and 2). As a result, inhibition of new leaf development, root growth, or storage components are common symptoms of Ca deficiency. Even though Ca^{2+} is essential for translocation of elements in the plants, it moves through the xylem and not the phloem; therefore, Ca is considered an immobile nutrient with deficiency appearing in new growth first. Magnesium is a principal component of chlorophyll, a structural component of ribosomes, and is required for phosphate transfer from ATP. Although Mg^{2+} moves through the soil and into the plant in much the same way as Ca^{2+}, it behaves quite differently in the plant. Deficiency symptoms associated with Mg^{2+} appear in older leaves first, as it is mobile within the plant (Table 2). Because of its role in chlorophyll and protein synthesis, Mg^{2+} deficiency appears similar to N deficiency resulting in chlorotic plants, although this symptom typically first appears as interveinal chlorosis and only causing complete chlorosis in cases of extreme deficiency.

Sulfur

Similar to Ca and Mg, S is often found in large quantities in soil depending primarily on parent material and climate. However, S differs from Ca and Mg in that it can exist as an anion (SO_4^{2-}). Sulfate retention on the soil is, therefore, impacted by the abundance of variable-charge minerals that increase the soil's AEC as pH decreases. Sulfur is similar to N in that organic matter is an important pool in most soils. More than 90% of the S present in noncalcareous soils resides in the organic pool. Therefore, cycling of organic S is a key component of the soil S cycle. Like N, the cycling of S by microorganisms is reduced under acidic conditions. Plant-available S is present as adsorbed and solution SO_4^{2-}. Historically, sulfur deficiency has been considered rare due to high sulfur deposition rates from the burning of fossil fuels. The decline in S deposition due to reduced S emissions has increased the incidence of S deficiency, particularly in high-yielding crops grown on deep sandy soils with low organic matter contents or on soils that developed from parent materials low in S. Plants primarily absorb SO_4^{2-} from the soil solution; however, they can also absorb thiosulfate ($S_2O_3^{2-}$) from the soil solution or absorb very small quantities of sulfur dioxide (SO_2) through their leaves. Sulfur is contained in and required for synthesis of amino acids, which are essential in protein formation. Sulfur is also required for the formation of chlorophyll. In legumes S promotes nodulation. Because of its role in chlorophyll and amino acid formation, S deficiency closely resembles N deficiency; however, S is not as mobile as N in the plant and therefore symptoms should be exhibited in younger tissue first.

Concentrations of SO_4-S in the soil solution of most temperate zone soils ranged from 5 to 20 mg SO_4-S per liter, higher than the 3–5 mg SO_4-S per liter required for the optimum growth of most plants. However, recent S deficiencies have been reported globally due to a combination of factors, the primary factor being a marked decrease in S deposition due to air pollution-control measures. Sulfate deposition has clearly decreased over the past 20 years as indicated by the National Atmospheric Deposition Program. For example, the average total wet deposition of sulfate at the Huntington Wildlife Station in Essex County, NY, USA was 22 kg ha^{-1} for the period of 1979–83 and decreased by 43% to 14 kg ha^{-1} for the period of 2003–07(NADP, 2008). This decrease in atmospheric deposition combined with increased crop yields and decreased agronomic S inputs is expected to contribute to increasing S deficiencies in crops (McGrath and Zhao, 1995). These predictions have been supported by recent studies showing increased yield responses to S fertilization in previously nonresponsive soils (Chen *et al.*, 2008).

Micronutrients

The eight essential micronutrient elements are just as important to plant nutrition as the macronutrients; they simply are required in very small, or trace, amounts by plants. The role of each of the essential micronutrient elements in plant nutrition is summarized in Table 1. A deficiency of any of the essential micronutrients results in similar reductions in plant health and vigor as a deficiency of any of the macronutrient elements. Unlike the macronutrients, the range between deficient and toxic levels for many of the micronutrients is generally narrow. Toxic levels of available nutrients may result from over application of fertilizer materials (e.g., B and Mo), or waste residuals such as biosolids (e.g., Cu and Zn). Toxic levels of some micronutrients may also result from soil conditions, such as low pH (e.g., Mn and Fe) or water-logged conditions (e.g., Mn).

Like the macronutrients, micronutrient elements may occur in soil as constituents of primary and secondary minerals or organic matter, adsorbed on mineral and organic matter surfaces, and in soil solution. The importance of any of these solid phases to the supply or buffering of plant-available ionic forms in soil solution depends on the micronutrient and the soil's condition. The ionic form of each of the essential micronutrient elements taken up by plants, summarized in Table 1, provides important information about their behavior in soil. The available forms of Cu, Mn, Fe, Ni, and Zn are metallic cations, whereas B, Mo, and Cl are anions.

As the micronutrients are needed by plants in such small amounts, most soils contain sufficient quantities to satisfy plant needs; however, the amount of available micronutrients in soil solution can be significantly affected by several factors, most notably soil pH (Figure 4). For example, Fe comprises approximately 4% of the earth's crust and is, on average, the fourth most abundant element in soil. It is a constituent of numerous common primary and secondary soil minerals, including olivine, siderite, hematite, goethite, and ferrihydrite. However, the solubility of these common Fe minerals is exceedingly low, resulting in very low concentrations of plant-available Fe^{2+} and Fe^{3+} in soil solution, and deficiencies commonly occur in soils with abundant levels of total Fe, especially where soil pH exceeds 6.5.

Similar to Fe, the other transition metal micronutrients Cu, Mn, Ni, and Zn are extremely sensitive to pH. At high pH all of these metals precipitate as insoluble carbonates and hydroxides. In addition, Cu and Zn are known to bind strongly to variable-charge minerals via chemisorption (specific sorption). For these reasons, Cu, Fe, Mn, Ni, and Zn availability decreases with increasing pH and are commonly deficient above pH 8. However, very acidic soils can have excessive availability to the point of plant toxicity. Molybdenum is the only trace metal micronutrient that becomes more available with an increase in pH above 6 (Figure 4).

There are several other factors or soil properties that govern processes of micronutrient sorption and desorption. These include soil organic matter content, soil texture, CEC, and soil aeration. The influence of soil organic matter, soil texture, and CEC on micronutrient behavior was discussed in the Section Soil Characteristics Contributing to Nutrient Supply. Soil aeration influences metallic micronutrient availability by favoring specific oxidation states of these elements. For example, in water-logged soils the concentration of dissolved oxygen in soil solution is depleted by microbial oxidation of soil organic matter. Under these conditions, the lower valence state, or reduced form, of the metallic micronutrients is favored. In general, the reduced form of the metallic micronutrients is more soluble and available, including Fe, Mn, and Cu.

Another important mechanism responsible for maintaining adequate levels of the metallic micronutrient elements to support plant growth in soil solution is called 'chelation.' Numerous organic molecules in soil can form organometallic complexes with these micronutrients. Chelation protects metallic ions from precipitation and specific sorption and increases micronutrient availability. The chelation of Fe, Cu, Zn, Mn, and Ni increases their concentration in soil solution and movement to plant roots by mass flow or diffusion. There are a number of naturally occurring chelating agents in soil formed from root and microbial exudates, including oxalic and citric acids. A number of synthetic chelates have also been used to enhance micronutrient availability, including ethylenediaminetetraacetic acid (EDTA), ethylenediamine bis (2-hydroxyphenyl)acetic acid (EDDHA), and hydroxy-2-ethylenediaminetriacetic acid (HEEDTA).

Molybdenum is the only trace metal micronutrient that becomes less available with a decrease in pH below 6 (Figure 4). The explanation for this is that Mo exists as an anion in solution (molybdate) that is somewhat susceptible to strong ligand-exchange reactions similar to P. For this reason, it is observed that Mo availability decreases with decreasing pH due to ligand-exchange reactions onto variable-charge minerals.

Like all micronutrients, B is found in geologic materials and organic matter and is typically slowly released via dissolution, desorption, and mineralization. As B often exists as an anion, it is usually bound to the soil AEC of variable-charge minerals. As a result, increases in pH that precipitate Al hydroxide minerals provide a surface for B to sorb onto, thereby decreasing B availability. The range between sufficient and toxic levels of available B is quite narrow, and certain crops are especially sensitive to excessive B, whereas others are more sensitive to B deficiencies. For example, most cereal crops, cotton, and soybean have low tolerance to high levels of available B, whereas most of the Brassicaceae family crops, alfalfa, and apples tend to be more sensitive to B deficiencies.

Among micronutrients, Cl is unique in that it exists primarily in soil solution, with only small quantities in mineral and organic soil fractions. Adsorption of Cl^- to mineral surfaces is negligible; therefore, it is extremely mobile in soils. The principle source of soil Cl is salts in the soil parent material and atmospheric deposition from volcanic emissions or marine aerosols in coastal areas. Chloride is also a principle component of the most common K fertilizer KCl.

Micronutrient fertilizer sources and practices

In most arable soils, adequate levels of available micronutrients can be achieved by managing the soil conditions that influence their supply to plants, such as soil acidity, aeration, and soil organic matter. However, in very coarse textured or highly weathered soils where large quantities of plant biomass are harvested and the supply of micronutrients is low, the soil supply may need to be supplemented through the use of fertilizers in order to optimize crop yield and plant health. As micronutrients are needed in such small quantities and due to their potential toxicity at high levels, very low (e.g., 0.5–5 $kg\,ha^{-1}$) and uniform applications are required. Micronutrient fertilizers are commonly applied to soil by blending with macronutrient fertilizers to improve handling and increase uniformity of application. Micronutrient fertilizers are commonly soluble salts or, in the case of the metallic micronutrients, synthetic chelates. In some cases, foliar applications may be used effectively to apply micronutrients to address a deficiency where soil applications are not convenient or possible (i.e., in-season application to annual crops or perennial fruit crops) or where soil conditions (e.g., high pH) may render soil-applied nutrients unavailable.

Summary

As a discipline, soil fertility and plant nutrition encompasses management of the soil environment to provide the essential nutrients in the required amounts to plants for optimum performance. Essential nutrients are those elements that play a vital role in plant growth, development, reproduction, or metabolic functions. Each nutrient is required at a specific concentration in plant tissue, below which normal plant functions are restricted. Carl Sprengel's theory of the minimum is a foundational principle in soil fertility, stating that if any of the essential nutrients are present below their critical

concentration then that nutrient is limiting, regardless of the amount of other nutrients present. Therefore, soil fertility evaluation to quantify the amount of available essential nutrients present is the basis for any soil fertility and plant nutrition management program. Multiple factors beyond just nutrient concentration in the soil influence the ability of the soil to supply nutrients to the plant and also the ability of the plant to take up and utilize those nutrients. The chemical, biological, and physical soil properties and processes influence plant nutrient utilization as well as other environmental factors such as pest pressure, climate, and crop management practices. Therefore, soil fertility and plant nutrition is an applied science that integrates all of the soil and crop management disciplines to provide optimum nutrient supply to plants for a specific goal (e.g., plant production for food, fiber, energy, or landscape esthetics) while protecting natural resources and environmental quality.

Glossary

Carbon sequestration Carbon storage in soil and plants.

Climate forcing The difference between solar energy reaching the earth's surface and energy (both light and heat) radiated back to space. A positive forcing warms the biosphere.

Gas flux The movement of a gas molecule into or out of an ecosystem.

Life cycle assessment A full accounting of the environmental consequences of a product from creation to disposal.

Mitigation Reducing the emission of greenhouse gases to alleviate the severity of climate change harm.

Radiative energy Energy transmitted by electromagnetic waves.

Sources and sinks Places within the biosphere where carbon, nitrous oxide, and other molecules are either released (source) or stored (sink).

Introduction

Greenhouse gases (GHGs) make up a tiny proportion of today's atmosphere but make life on earth possible. In their absence, the light absorbed by the earth's surface and re-emitted as long-wave radiation (heat) would be immediately lost to space. Instead, a substantial fraction of the 161 W m^{-2} absorbed and reemitted by the earth's surface is temporarily held in the atmosphere, warming the biosphere to an inhabitable temperature. In the absence of GHGs the earth's surface would be frozen with an average surface temperature of −18 °C (Ramanathan, 1988).

It thus stands to reason that changes in atmospheric GHG concentrations will lead to changes in the earth's surface temperature, and, although radiative feedbacks make the story more complex, in general this is in fact the case. As GHG concentrations have increased in the atmosphere, the biosphere has correspondingly warmed (IPCC, 2007). Almost all of the recent increase in global surface temperatures can be attributed to increases in GHG concentrations (IPCC, 2007).

In what way has agriculture played a role in GHG changes? Of the six major radiative sources of climate forcing since 1750 (**Figure 1**), agriculture has directly influenced five: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), tropospheric ozone (O_3), and black carbon (IPCC, 2001). These sources are together responsible for approximately 80% of contemporary climate forcing, and agricultural activities affect some GHGs more than others. Overall, agriculture is estimated to directly contribute 10–14% of total global anthropogenic GHG emissions annually (Smith *et al.*, 2007; Barker *et al.*, 2007). This includes N_2O emissions from soil (38% of agriculture's direct contribution) and manure (7%), enteric emissions of CH_4 from ruminant animals (32%), and N_2O and CH_4 from biomass burning (12%).

Not included in this estimate are GHGs from land-cover change due to agricultural expansion; the manufacture of agricultural inputs such as fertilizer and pesticides; or post-harvest activities such as processing, transport, refrigeration, and food management. Land-cover change emits both CO_2 and N_2O to the atmosphere, and in total is responsible for another 12–17% of global GHG emissions (Barker *et al.*, 2007; van der Werf *et al.*, 2009). The manufacture of nitrogen fertilizers and pesticides together adds another 0.6–1.5% to agriculture's global GHG footprint (calculated from Vermeulen *et al.*, 2012), and postproduction activities add at a minimum another 3% (Vermeulen *et al.*, 2012). Including these sources brings agriculture's GHG footprint to 26–36% of all anthropogenic GHG emissions.

The purpose of this article is to describe the ways that agricultural soils have contributed to the GHG burden of the atmosphere, and – as importantly – to show how future agricultural management might mitigate the GHG build-up and thereby contribute to climate stabilization.

In the pages that follow are descriptions of agricultural sources and sinks of the major GHGs affected by agriculture and potential mitigation strategies related to soil management. Because agriculture is a systems enterprise in that all of its parts are interconnected, mitigation must also be approached from a systems and not just a soils standpoint. The penultimate section presents the case for a life cycle assessment of entire agricultural systems in the context of a Midwest US

cropping system. Finally, future mitigation is discussed in the context of biofuels and carbon capture and sequestration technologies.

Nitrous Oxide

The significance of N_2O stems not from its atmospheric mass, which is small, but from its high global warming potential (GWP). GWP is a measure of the capacity of a well-mixed gas to trap heat once emitted to the atmosphere (IPCC, 2001). Its value is relative to a reference gas, by convention CO_2, and its magnitude depends on both its efficiency as a GHG and its atmospheric lifetime – long-lived gases will have high GWPs even if their heat trapping efficiency is relatively low. Nitrous oxide has a GWP of approximately 300 over a 100-year time horizon (Table 1), meaning that it traps heat in the atmosphere 300 time more effectively than CO_2. Thus, a kilogram of N_2O emitted to the atmosphere is equivalent to approximately 300 kg of CO_2 emitted at the same time. Conversely, avoiding the emission of 1 kg of N_2O is equivalent to sequestering approximately 300 kg of CO_2.

Sources and Sinks of Nitrous Oxide in Agricultural Soils

Agriculture is responsible for approximately 84% of the global anthropogenic N_2O flux of 8.1 Tg yr^{-1} and approximately 38% of the total global flux (anthropogenic+natural sources) of 17.7 Tg yr^{-1} (**Figure 2(a)**; Mosier *et al.*, 1998a; Robertson, 2004). A small portion (0.5 Tg yr^{-1}) of the N_2O flux is due to biomass burning, primarily in the tropics and subtropics when crop residues are burned and when new land is cleared for row crops and pastures. A larger amount (2.1 Tg yr^{-1}) is associated with microbial activity during animal waste treatment. Nitrification and denitrification, the primary microbial pathways for N_2O production, occur readily in manure and other animal waste products when conditions are right. A still larger source of anthropogenic N_2O is agricultural soils, which emit approximately 4.2 Tg N_2O per year globally or approximately 52% of the total anthropogenic N_2O source. Nitrification and denitrification also occur readily in soils, where their rates are stimulated by the abundant nitrogen that cycles rapidly in virtually all cropped ecosystems.

During nitrification, ammonium (NH_4^+) added as fertilizer or mineralized from soil organic matter, crop residues, or other organic inputs is oxidized by nitrifiers to nitrite (NO_2^-) and eventually to nitrate (NO_3^-) in a series of reactions that can also produce N_2O.

$$\begin{array}{ccccccc} & & N_2O & & N_2O & & \\ & & \uparrow & & \uparrow & & \\ NH_4^+ & \longrightarrow & NH_2OH & \longrightarrow & NO_2^- & \longrightarrow & NO_3^- \end{array} \quad [1]$$

Some N_2O is produced from the chemical decomposition of hydroxylamine (NH_2OH), an intermediate formed during the oxidation of NH_4^+ to NO_2^-. Significantly more N_2O is produced by nitrifiers under low oxygen conditions, when they use NO_2^- as an electron acceptor, a pathway they have in common with denitrifiers (Robertson and Groffman, 2007).

Denitrifiers use NO_3^- and other oxidized forms of nitrogen as an electron acceptor during cellular respiration when oxygen is in limited supply. Nitrous oxide is an intermediate product that can either escape to the atmosphere or be further reduced to N_2 gas by the enzyme N_2O reductase, thereby closing the global nitrogen cycle.

$$\begin{array}{ccccccccc} 2NO_3^- & \longrightarrow & 2NO_2^- & \longrightarrow & 2NO & \longrightarrow & N_2O & \longrightarrow & N_2 \\ & & & & \uparrow & & \uparrow & & \uparrow \end{array} \quad [2]$$

Each transformation step is mediated by a specific inducible enzyme, such that delays in the production of one enzyme can lead to the accumulation and release to the environment of its substrate: N_2O in the case of delays in N_2O reductase formation (Bergsma *et al.*, 2002; Robertson and Groffman, 2007). Theoretically, atmospheric N_2O can also diffuse into cells and be reduced directly to N_2, though in practice this appears to be a negligible global sink for N_2O: rarely are negative soil N_2O fluxes detected.

Soil N_2O fluxes are thus largely controlled by the same environmental factors that control nitrification and denitrification: Soil temperature and moisture as they affect microbial activity in general and the diffusion of oxygen to microsites where nitrification and denitrification occur; soil carbon as it affects the availability of electron donors to heterotrophic denitrifiers as well as the consumption of oxygen in soil microsites; and the availability of soil inorganic nitrogen (NH_4^+ for nitrifiers and NO_3^- for denitrifiers). Soil inorganic nitrogen is derived from the mineralization of soil organic matter and from the addition of synthetic or organic fertilizers and animal manure. Soil structure also plays an important role in N_2O production in that sandy or otherwise poorly structured soils have fewer

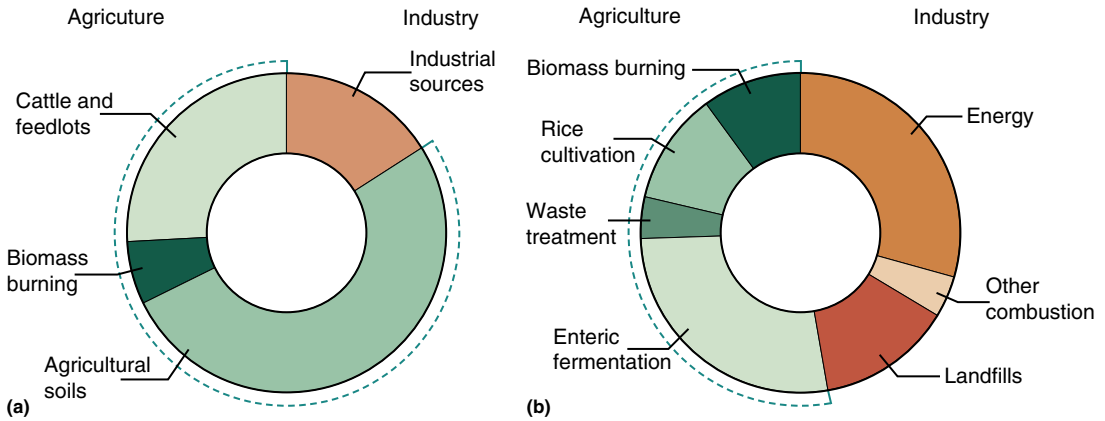

Figure 2 Anthropogenic sources of (a) nitrous oxide and (b) methane. Redrawn from Robertson, G.P., 2004. Abatement of nitrous oxide, methane, and the other non-CO_2 greenhouse gases: The need for a systems approach. In: Field, C.B., Raupach, M.R. (Eds.), The Global Carbon Cycle. Washington, DC: Island Press, pp. 493–506 and based primarily on data in IPCC, 2001. Climate change 2001: The scientific basis. New York, NY: Cambridge University Press.

anaerobic microsites than well-structured or heavier soils with higher clay content.

In upland soils, denitrification occurs primarily within soil aggregates (Sexstone *et al.*, 1985) or within soil organic matter particles (Parkin, 1987) where ample carbon fuels oxygen consumption at rates greater than oxygen can be immediately replaced via diffusion from the bulk soil atmosphere. Diffusion of oxygen is substantially inhibited by the water film that surrounds biologically active soil aggregates and particles. Denitrification also occurs in submerged low-oxygen wetland soils, riparian zones, and stream and lake sediments, and insofar as these habitats receive nitrate leached from cropped soils, agriculture is also a major source of N_2O from these environments (Ostrom *et al.*, 2002; Whitmire and Hamilton, 2005; Beaulieu *et al.*, 2011).

It is not surprising, then, that arable soils, managed to cycle carbon and nitrogen rapidly in order to support high crop productivity, produce large quantities of N_2O particularly in mesic or irrigated environments. That for any given cropping system N_2O fluxes are directly related to nitrogen inputs should also come as no surprise: typically fluxes are highest following fertilization (**Figure 3**) or the incorporation of nitrogen-rich residues such as leguminous cover crops into soil. Production of nitrous oxide during these periods can dominate the annual soil flux. Moreover, the rate of nitrogen fertilizer addition is generally the best predictor of N_2O flux in both cropped and pasture systems: On average, approximately 1% of the nitrogen applied to cropland is emitted as N_2O–N (Bouwman *et al.*, 2002) and this emission factor is the basis for the Intergovernmental Panel on Climate Change (IPCC) GHG inventory estimates of N_2O flux from cropped soils (De Klein *et al.*, 2006). Recent evidence suggests that this value will be high for nitrogen fertilizer levels that exceed crop nitrogen needs (McSwiney and Robertson, 2005; Hoben *et al.*, 2011) – in these cases the excess nitrogen available to nitrifiers and denitrifiers will result in still higher N_2O fluxes.

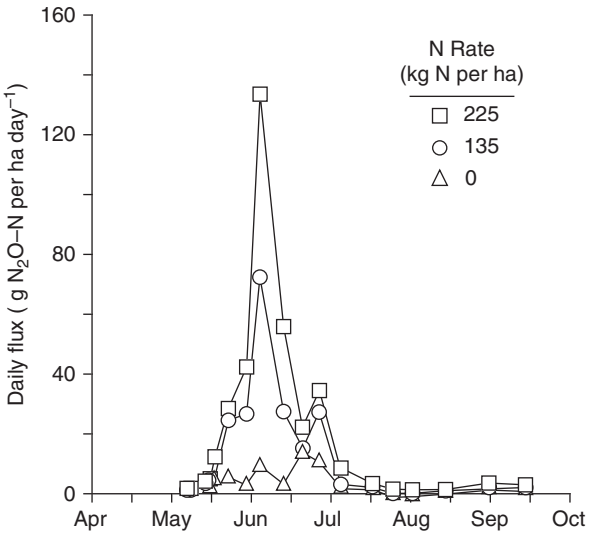

Figure 3 Nitrous oxide (N_2O) flux response to fertilizer addition. Reproduced from Hoben, J.P., Gehl, R.J., Millar, N., Grace, P.R., Robertson, G.P., 2011. Nonlinear nitrous oxide (N_2O) response to nitrogen fertilizer in on-farm corn crops of the US Midwest. Global Change Biology 17, 1140–1152.

Mitigation of Nitrous Oxide in Agricultural Soils

Because there are no significant environmental sinks for N_2O, mitigation is best pursued by avoiding or attenuating known N_2O sources. For agriculture, this means slowing the microbial conversion of inorganic nitrogen (NH_4^+, NO_3^-) to N_2O by altering one or more of the environmental factors that affect the conversion – carbon, oxygen, and soil nitrogen – or by biochemically inhibiting these pathways using soil additives.

Nitrification, for example, can be managed to reduce N_2O production during manure handling by creating an anaerobic environment that suppresses nitrifier metabolism. By storing

manure in anaerobic lagoons, nitrification will be inhibited by the lack of oxygen. Although anaerobic conditions typically promote denitrification, without the nitrate provided by nitrifiers this pathway will be substrate-limited and denitrifiers will produce less N_2O.

In soils, N_2O mitigation is more complex. Nitrification is necessary in order to provide nitrate to plants, and generally occurs very quickly in arable soils (Robertson and Groffman, 2007) whether the source of ammonium is mineralized soil organic matter, manure, or ammonium-based fertilizers such as urea or anhydrous ammonia. In some soils, nitrification can be inhibited with commercial chemical additives such as nitrapyrin and dicyandiamide. These compounds slow ammonium oxidation and thus mitigation is achieved both by reducing nitrifier-derived N_2O and reducing the nitrate supply to denitrifiers. Field experiments suggest that N_2O fluxes can be reduced by inhibitors to 40% in some soils (Akiyama *et al.*, 2010; Halvorson *et al.*, 2010), though very little in others (e.g., Parkin and Hatfield, 2010). In some cases, the reduction may be simply delayed production – nitrification is inhibited, not prevented, such that added ammonium will eventually be nitrified and hence available for N_2O production. But if less fertilizer is applied because plant fertilizer-use efficiency is improved, then the avoided N_2O loss will be permanent. Likewise, theory suggests that urease inhibitors ought also to be effective for reducing N_2O fluxes by slowing the conversion of urea to ammonium, but results of field trials are even more mixed than those for nitrification inhibitors (Akiyama *et al.*, 2010; cf. Halvorson *et al.*, 2010).

A more direct means for N_2O mitigation in agricultural soils is more precise nitrogen fertilizer management (Millar *et al.*, 2010), i.e., reducing the availability of excess inorganic nitrogen to nitrifiers and denitrifiers. Because the best predictor of N_2O fluxes from soils is nitrogen availability, it makes sense that the most effective mitigation strategy is to reduce fertilizer additions to the lowest levels necessary to ensure optimal crop yields. Millar *et al.* (2010) suggested that N_2O fluxes from agricultural soils could be reduced 50% if farmers adopted more conservative fertilizer practices.

How can fertilizers be used more conservatively? Four factors contribute most importantly to fertilizer-use efficiency: fertilizer rate, placement, timing, and formulation. Rates of fertilizer application vary widely across the globe even for the same crop. In China, rates are exceedingly high (Vitousek *et al.*, 2009) and not much based on expected yields. In North America, nitrogen fertilizer rates are typically based on a yield-goal approach wherein a projected yield is multiplied by a standard factor to provide a recommended nitrogen rate, sometimes debited for nitrogen credits provided by a preceding legume crop, manure application, or soil nitrogen tests. However, even this approach is not very conservative. A more robust Maximum Return to Nitrogen (MRTN) approach (Sawyer *et al.*, 2006) is instead based on nitrogen field trails, fertilizer costs, and commodity prices. Recommended rates for a particular region are based on the asymptotic response of that crop to incremental nitrogen additions. Data from hundreds of field trials are used to identify the nitrogen rate at which the cost of further nitrogen fertilizer additions is not paid for by the economic return of additional yield. Though MRTN is now the university-recommended approach for corn in seven Midwest US states, it is not yet widely adopted (Stuart *et al.*, 2012). Quantitative crop models such as Adapt-N (Melkonian *et al.*, 2007) and Maize-N (Setiyono *et al.*, 2011) can provide even more precise nitrogen recommendations based on still more localized climate and soils information.

Fertilizer placement refers to putting nitrogen fertilizer where it is most likely to be taken up by nearby plants or kept from volatilizing to the atmosphere as ammonia (NH_3). Subsurface banding, for example, can achieve higher fertilizer-use efficiencies, as can nitrogen application calibrated to the spatial distribution of crop nitrogen needs across a field. This spatial pattern of nitrogen needs can be estimated from the spatial patterns of prior crop yields across the field – readily provided by yield monitors on modern grain combines. Or nitrogen needs can be estimated in real time during the growing season using spectral sensors that indicate a growing crop's nitrogen stress based on leaf chlorophyll content (Raun *et al.*, 2002; Gehl and Boring, 2011). The optimal placement of fertilizer nitrogen across a cropped field can substantially reduce nitrogen fertilizer rates without affecting crop yields (e.g., Scharf *et al.*, 2005; Mamo *et al.*, 2003).

The timing of nitrogen fertilizer application can also affect nitrogen fertilizer-use efficiency and, by inference, N_2O fluxes. Adding nitrogen closer to the time of plant nitrogen need will leave less nitrogen available in the soil for N_2O production. This can be achieved by avoiding fall fertilization of spring planted crops, by splitting fertilizer applications into smaller portions added more frequently (e.g., some at planting and the remainder after the plants are growing), or by adding fertilizer to irrigation water.

Fertilizer formulation can also affect N_2O fluxes, though the effects are not consistent among the major fertilizer types such as anhydrous ammonia, urea, manure, or urea ammonium nitrate. For this reason, the IPCC GHG inventory methods make no distinctions among fertilizer types (De Klein *et al.*, 2006), nor do other mitigation protocols (Millar *et al.*, 2010, 2012; CAR, 2012). Slow-release formulations, however, are designed to delay the release of nitrogen to the soil solution by coating fertilizer particles with sulfur, polymers, or other temperature- or moisture-sensitive compounds, and to the extent that they can improve fertilizer-use efficiency – and thereby reduce fertilizer rates for the same yield – they ought to reduce N_2O fluxes. There are currently too few successful N_2O field trials to judge their effectiveness.

Mitigation of N_2O through carbon market cap and trade programs has only recently become available with the 2012 approvals of nitrogen management protocols by the major carbon registries. The American Carbon Registry (ACR), Verified Carbon Standard (VCS), and Climate Action Reserve (CAR) have approved methodologies that allow payments to farmers for reducing N_2O emissions by changing fertilizer practices. In one of ACR's methods, the protocol is based on the application of a complex quantitative N_2O model not thoroughly field tested. In other cases (ACR, CAR, and VCS), the method is based on fertilizer rate reductions by whatever means a farmer chooses to use – by more precisely predicting fertilizer need (e.g., using the MRTN rather than yield-goal fertilizer estimators), or the use of precision application technologies, nitrification inhibitors, slow-release formulations, or other strategies that reduce nitrogen fertilizer use without

affecting crop yield. Avoided N_2O emissions are credited using the relationships between nitrogen fertilizer use and N_2O emission noted above – either linear as for the IPCC methodology (De Klein *et al.*, 2006) or nonlinear as for more recent analyses (Millar *et al.*, 2010). Avoided N_2O, determined as the difference between estimated past emissions during a 5-year baseline period and estimated emissions during the credit period, is multiplied by its GWP (298) to provide a saleable CO_2 credit that can then be traded on carbon markets (Millar *et al.*, 2010).

Methane

Globally, agriculture is responsible for approximately 53% of the total anthropogenic CH_4 flux of 344 Tg CH_4 per year (**Figure 2(b)**), itself approximately 58% of the total global CH_4 flux of 598 Tg CH_4 per year (Mosier *et al.*, 1998b; Sass *et al.*, 1999; IPCC, 2001; Robertson, 2004). Agricultural sources of CH_4 include enteric fermentation by anaerobic bacteria within ruminant animals such as cattle and sheep, which accounts for approximately 52% of agricultural emissions; methanogenesis by anaerobic bacteria in submerged soils during rice cultivation (approximately 19% of agricultural emissions); biomass burning when crop residues are burned or land is cleared for agricultural production (approximately 19% of agricultural emissions); and methanogenesis during the handling and treatment of animal wastes (approximately 10%).

Sources and Sinks of Methane in Agricultural Soils

Biological CH_4 production is the result of methanogenesis carried out by methanogens – a class of microbes that inhabit anaerobic environments such as submerged soils and cow rumens and derive their energy from substrates formed during fermentation or from fermentation derivatives (McGill, 2007). In lowland rice, much of the CH_4 produced depends on the plant itself, which provides both photosynthate to methanogens inhabiting the rhizosphere and a pipeline to the atmosphere. While some CH_4 exits rice sediments via ebullition – bubbles formed on the accumulation of sufficient gas that float to the surface – much also exits through the rice plant itself: some portion of the CH_4 produced near its roots passes from sediments through aerenchyma in the rice stem and out open stomata to the atmosphere.

In well-aerated soils everywhere, CH_4 is not produced but rather consumed. Methane consumption is performed by methanotrophs, a class of microbes with the capacity to oxidize CH_4 to CO_2 for energy. In so doing, methanotrophs provide an important ecosystem service: globally, they remove from the atmosphere approximately 30 Tg CH_4 per year. Although it is not a large sink relative to the total global flux of 598 Tg CH_4 per year, it is nevertheless equivalent to the annual loading rate for CH_4 in the atmosphere; without methanotrophs, the atmosphere would be accumulating CH_4 at approximately twice today's rate. Thus, the fact that land conversion to agriculture reduces CH_4 oxidation by 60–90% in most soils (Mosier *et al.*, 1991; Smith *et al.*, 2000) is significant.

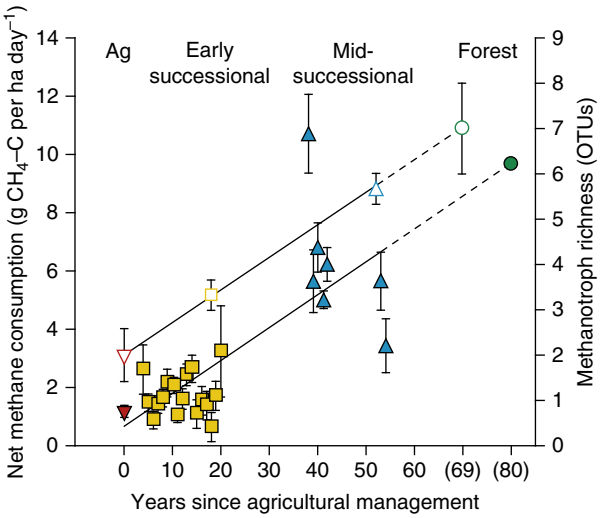

Figure 4 The simultaneous recovery of methanotroph diversity (in operational taxonomic units or OTUs; open symbols) and methane consumption (closed symbols) in ecological succession from row-crop fields (Ag, green) through early (yellow) and mid-successional (blue) fields to mature forest (orange) at a site in southwest Michigan, USA. Reproduced from Levine, U., Teal, T.K., Robertson, G.P., Schmidt, T.M., 2011. Agriculture's impact on microbial diversity and associated fluxes of carbon dioxide and methane. ISME Journal 5, 1683–1691.

Reduced CH_4 oxidation capacity may be related to faster nitrogen cycling in arable soils (Hütsch *et al.*, 1993) – ammonium, either mineralized from crop residues or added as fertilizer, appears to competitively inhibit the enzymes involved in CH_4 oxidation (Gulledge and Schimel, 1998). Agronomic management of the soil environment, such as tillage, appears to have little effect on CH_4 oxidation (Burke *et al.*, 1999; Suwanwaree and Robertson, 2005). Recent results suggest that microbial diversity may also influence the CH_4 oxidation capacity of soils. Levine *et al.* (2011) found a remarkable positive association between CH_4 oxidation and methanotroph diversity along a 100+-year successional gradient (**Figure 4**).

Mitigation of Methane Fluxes in Agricultural Soils

Rice management provides a ready means to attenuate CH_4 production in paddy rice fields. High-yielding varieties tend to have substantially lower CH_4 emissions (Corton *et al.*, 2000; van der Gon *et al.*, 2002) owing to more efficient photosynthate use – higher-yielding plants allocate more fixed carbon to biomass and transmit less to methanotrophs in the rhizosphere.

Residue management and drainage also affects CH_4 fluxes in lowland rice. Encouraging the decomposition of residues before flooding through tillage or composting can substantially diminish CH_4 emissions after flooding (Wassmann *et al.*, 1993). Likewise, drainage for several-day periods during the growing season can also markedly reduce seasonal emissions (Lu *et al.*, 2000) due to accelerated organic matter decomposition as soils become aerated during drainage periods.

Recovering the lost oxidation potential of agricultural soils represents another potential mitigation opportunity. To date,

however, no management practices have been identified that can enhance CH_4 oxidation in cropped soils. Only after abandoning cropland to secondary succession (e.g., Robertson *et al.*, 2000) does soil CH_4 oxidation return, although new insights into the role of microbial community composition (Levine *et al.*, 2011) may eventually provide some new management insights as well.

Reactive Nitrogen Oxides

Oxides of nitrogen, most notably nitric oxide (NO), are also emitted from agricultural systems. Because NO oxidizes quickly in the atmosphere to form NO_2 and other compounds, most fluxes of reactive oxidized N are reported collectively as nitrogen oxides (NO_x), the sum of all such forms. NO_x is not itself radiatively active and is therefore not explicitly a GHG. Nevertheless, emitted NO_x leads to the formation of tropospheric ozone (O_3), which is both a GHG (**Figure 1**) and toxic to crops and humans.

Agriculture is responsible for approximately 25% of the global anthropogenic NO_x flux, which itself represents approximately 80% of the total terrestrial NO_x flux (Galloway *et al.*, 2004). Of the agricultural flux, Galloway *et al.* (2004) estimated that approximately 30% is derived from agricultural soils, with the remainder from the burning of crop residue (27%) and native vegetation as land is cleared for agriculture (44%). Davidson and Kingerlee (1997) estimated that agricultural soils worldwide are responsible for 5.5 Tg of NO_x–N emissions annually, approximately twice the estimate made by Galloway *et al.* (2004). Jaeglé *et al.* (2005) used top-down atmospheric modeling to estimate 2.5–4.5 Tg NO_x–N per year from fertilized agricultural soils.

The role of NO_x in tropospheric photochemistry is substantial: elevated NO_x leads to the oxidation of atmospheric hydrocarbons and carbon monoxide, which leads in turn to O_3 production. Conversely, low NO_x concentrations lead to O_3 consumption (Chameides *et al.*, 1992).

Sources and Sinks of Nitrogen Oxides in Agricultural Soils

Soil-derived NO_x is from NO produced during nitrification and denitrification (Robertson and Groffman, 2007). When hydroxylamine (NH_2OH in eqn [1]) is oxidized to nitrite (NO_2^-) during nitrification, intermediary compounds can result in the formation of NO (as well as N_2O) that then escapes to the atmosphere. In denitrification, NO is formed by the enzyme nitrite reductase (nir) and is either further reduced to nitrous oxide via nitric oxide reductase (nor) or escapes to the atmosphere. Because denitrifier enzymes are induced sequentially, there is often a lag between the production of NO and its subsequent reduction to N_2O in soil, leading to a substantial opportunity for NO escape in environments where denitrification occurs sporadically following wetting events. This is the case in most arable soils, where NO_x fluxes can for short periods equal or exceed N_2O fluxes (e.g., Matson *et al.*, 1998). In general, however, annual global NO_x–N fluxes from cropland soils are approximately half the magnitude of N_2O–N emissions from cropland soils (Stehfest and Bouwman, 2006).

Mitigation of Nitrogen Oxides from Agricultural Soils

Because NO emitted from soils is formed during nitrification and denitrification, NO emissions are affected by the same environmental and management factors discussed earlier for N_2O. These include fertilizer rate, placement, timing, and formulation. There is evidence that some management factors such as no-till may have a different effect for NO than for N_2O (e.g., Liu *et al.*, 2006) but in general effects are consistently similar based on available data.

Carbon Dioxide

By mass, CO_2 is by far the largest source of radiative forcing in the atmosphere, responsible for >50% of the greenhouse warming that has occurred since 1750 (**Figure 1**). Most of this, of course, is from fossil fuel use, but a substantial portion is from the net release of CO_2 from soils when forests and grasslands are first cleared for agriculture. Before 1900, agricultural expansion in North America, Australia, Southern Africa, and Eastern Europe may have released as much as 100 Pg C from soils (Wilson, 1978), contributing as much as 25% of the increase in atmospheric CO_2 at that time (Paustian *et al.*, 1995). Today, approximately 16% of the global CO_2 flux is from deforestation (Canadell *et al.*, 2007), mostly in South America and Southeast Asia.

In well-established croplands, CO_2 emissions are largely confined to the use of fossil fuel during the manufacture and transport of fertilizers, pesticides, and other agrochemicals, as well as from changes in soil organic carbon (SOC) as affected by various management practices.

Sources and Sinks of Carbon Dioxide in Agricultural Soils

Soil carbon in agricultural lands can represent a net sink or source of CO_2 depending on cropping history and contemporary management. As described in Paustian *et al.* (1995), soil carbon stores typically decline 40–60% in the first 40–60 years following conversion to agriculture. The decline happens faster in the humid tropics and is even more abrupt in high-organic matter soils such as drained wetlands, but in general soils reach an equilibrium carbon content that is relatively stable for a given soil type and climate. Deviations from equilibrium values indicate CO_2 uptake from or release to the atmosphere, and occur due to management and climate change.

Net carbon storage in soils results from changes in carbon inputs, changes in decomposition rates, or both. Carbon enters soil primarily as plant residues – aboveground leaves, stems, and other tissues as well as belowground roots and their exudates. The rate at which this material decomposes largely determines whether soil carbon will accumulate: If more organic carbon enters the soil pool than can be readily oxidized by microbes and invertebrates, soil carbon stores will increase and the soil will become a net sink of CO_2. If biomass that enters the soil is readily decomposed, then there will be no net change in carbon stores. If decomposers oxidize soil organic matter faster than it is replaced by new biomass, then carbon stores will decline.

Decomposition is affected both by the quality of organic matter – the degree to which its chemical constituents are

readily metabolized by soil organisms – and the soil microclimate. Biomass with a high carbon:nitrogen ratio such as senesced leaves and stems and biomass with a high lignin content such as corn stalks and wood will decompose relatively slowly. Biomass with low carbon:nitrogen and lignin content such as legume leaves and stems will decompose rapidly.

Likewise, tillage accelerates decomposition by breaking apart soil aggregates that would otherwise delay decomposition of the carbon they contain by restricting the supply of oxygen to microbes within the aggregates (Sexstone *et al.*, 1985). Exposing this otherwise protected carbon to air leads to its rapid oxidation (Six *et al.*, 2000; Grandy and Robertson, 2007). Plowing also leads to higher soil surface temperatures as residue that would normally shade the soil from direct insolation is instead buried, further accelerating decomposition. Thus, management that affects the quantity and quality of organic matter inputs or the microenvironment where decomposition occurs can have profound effects on soil CO_2 emissions. In the absence of erosion, any change in organic soil carbon from year to year represents a net annual flux of soil CO_2.

Erosion presents a special case. Although erosion removes carbon from a particular location, it usually deposits carbon elsewhere in the landscape rather than oxidize it directly to CO_2. Often these locations are in toe-slope positions where the added soil can serve to bury existing carbon and thereby slow its decomposition, or particles can be washed into waterways or surface waters where they can accumulate in anaerobic sediments. Perversely, erosion can result in a carbon sink as decomposition slows in areas of deposition and carbon is replaced on the eroded sites (Harden *et al.*, 2008). Quine and van Oost (2007) estimated a sink capacity of approximately 26% for eroded soil.

Energy inputs and soil amendments can also represent sources of agricultural CO_2. Fossil fuel, usually diesel, is used to power equipment used for tilling, planting, and harvesting and for applying fertilizers, herbicides, and other inputs, and this fuel is emitted as CO_2 on use. Likewise, the fossil fuel used to manufacture herbicides and synthetic fertilizers represents a CO_2 cost of agriculture. As will be seen in the Section Synthesis: System-Wide Global Warming Impact, these costs are small but significant. The CO_2 cost of atrazine, for example, is 2.3 kg CO_2 per kg of active ingredient (750 g l^{-1}) (Gelfand *et al.*, 2013) and the CO_2 cost of nitrogen fertilizer manufacture – which uses CH_4 as a feedstock in addition to using fossil fuel to meet its temperature and pressure requirements – is 4.5 kg CO_2 per kg of N applied (Schlesinger, 1999).

Agricultural lime is another special case. Lime, as crushed limestone ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$), is commonly applied to agricultural land to counteract the acidity caused by nitrogen fertilizers and the removal of base cations in harvested biomass. The carbonate (CO_3^{-2}) in lime weathers to CO_2 or bicarbonate (HCO_3^-) depending on the strength of the weathering agent (Hamilton *et al.*, 2007). If the weathering agent is nitric acid, produced by nitrifying bacteria, then the carbon in lime is dissolved and released to the atmosphere directly, as in the equation:

$$CaCO_3 + 2HNO_3 \rightarrow Ca^{2+} + 2NO_3^- + H_2O + CO_2 \qquad [3]$$

If, however, the weathering agent is the weaker carbonic acid, produced by the dissolution of CO_2 from root and microbial respiration in soil solution, then the lime is transformed to bicarbonate, as in the equation:

$$CaCO_3 + H_2O + CO_2 \rightarrow Ca^{2+} + 2HCO_3^- \qquad [4]$$

Interestingly, the latter reaction consumes an additional mole of CO_2 from the atmosphere for every mole of $CaCO_3$ dissolved. Thus, lime dissolved by strong acid becomes a source of CO_2 whereas lime dissolved by weak acid becomes a CO_2 sink. Current evidence suggests that more lime is dissolved by carbonic than by nitric acid (West and McBride, 2005; Oh and Raymond, 2006; Hamilton *et al.*, 2007), resulting in sequestration equivalent to approximately 33% of the lime's carbon content. This is counterbalanced, however, by emissions from fossil fuel use during the mining and transport of lime (West and Marland, 2002), which is more than sufficient to offset its sequestration potential. Agricultural lime use may thus be largely neutral with respect to CO_2.

The growth of perennial vegetation represents a sink for CO_2 as carbon is captured in growing biomass both above and belowground. And because perennial crops are rarely tilled, CO_2 is also sequestered as SOC, which, because of persistent roots, can build soil carbon at even faster rates than can annual crops managed with no-till practices. For example, successional vegetation on abandoned farmland and perennial grasses planted as part of set-aside programs such as the US Department of Agriculture's Conservation Reserve Program (CRP) can sequester soil carbon at rates twice those of no-till annual crops (Robertson *et al.*, 2000; Gelfand *et al.*, 2011). However, replanting practices can have a major impact on the persistence of this stored carbon. Syswerda *et al.* (2011), for example, found that a large portion of the soil carbon stored by a 12-year-old hybrid poplar plantation was lost during harvest and reestablishment, due apparently to warmer and moister soils during early reestablishment that stimulated decomposition rates. Likewise, converting perennial cropland back to annual cropping – for example, the return of CRP lands to corn-soybean production – can release large amounts of CO_2 (and N_2O) even when conversion involves no-till management (Zenone *et al.*, 2011; Gelfand *et al.*, 2011), but especially when the soil is plowed (Grandy and Robertson, 2006; Ruan and Robertson, 2013).

Mitigation of Soil Carbon Dioxide Fluxes in Agricultural Soils

Mitigation of soil CO_2 fluxes generally involves increasing SOC stores. This can be accomplished by increasing the inputs of biomass carbon to soil, by reducing soil decomposition rates or both (CAST, 2011). Crops that produce abundant residue will sequester more soil carbon than those that do not; corn, for example, will produce 2–3 times more biomass than soybean and, if not harvested, corn residue will contribute more than soybean to building or maintaining SOC. Thus, continuous corn rotations will build soil carbon faster than corn–soybean rotations. Likewise, cover crops can help to build soil carbon by increasing the quantity or biochemical complexity of residue carbon inputs (Syswerda *et al.*, 2011).

The reduction of soil decomposition rates is generally accomplished through tillage management. No-till practices are one of the most widespread and effective ways to sequester soil carbon in most soils. Other forms of conservation tillage – strip tillage and shallow tillage, for example – can provide some of the benefit of no-till, but not as much (CAST, 2011).

However, no-till is not effective at storing soil carbon in all soils, and some have suggested that increased storage in the surface layers of many soils may be offset by lost carbon deeper in the profile (Baker *et al.*, 2007). Others (Kravchenko and Robertson, 2011) have pointed out that a failure to detect whole-profile carbon change with no-till is a consequence of low statistical power rather than the absence of effects, and the fact that most no-till soils show an increased surface soil carbon content is ample evidence for no-till carbon gain. No studies to date have shown statistically significant carbon declines below the A horizon of no-till soils.

Evidence to date suggests that all cropping system soils – unless continuously amended by exogenous inputs such as manure, biochar, or sewage sludge – will equilibrate at some soil carbon content less than that in the native ecosystem that existed before cultivation (Six *et al.*, 2002; Stewart *et al.*, 2007). Quantitative models suggest that this will occur within 60–100 years of management in most temperate region soils.

Evidence also suggests that carbon thus stored is at significant risk of re-release (CAST, 2011). Grandy and Robertson (2006), for example, showed that a substantial fraction of the soil carbon stored in a native never-plowed soil was released after a single plowing, which immediately destabilized soil aggregates to the same degree as in an adjacent field that had been plowed for >100 years. Permanent no-till is by far the preferred mitigation approach (Grandy *et al.*, 2006); although occasional light tillage may permit the persistence of some stored carbon, there is too little evidence to date to judge its effectiveness.

Synthesis: System-Wide Global Warming Impact

The balance of all GHG sources and sinks in a given cropping system for a particular year is termed the net GHG balance or net global warming impact (GWI). The GWI is calculated by summing all GHG fluxes (whether positive or negative) after first converting each to a CO_2-equivalent (CO_2e) basis. For N_2O and CH_4, this is performed by multiplying each by its respective 100 year GWP (Table 1; 298 for N_2O and 25 for CH_4). For N_2O (g CO_2e per ha day^{-1}) the equation is:

$$CO_2e\ (N_2O) = \frac{x_1\ \text{g}\ N_2O\text{–}N}{\text{ha} \times \text{day}} \times \frac{44\ \text{g}\ N_2O}{28\ \text{g}\ N_2O\text{–}N} \times \frac{365\ \text{days}}{1\ \text{year}} \times \frac{1\ \text{ha}}{10^4\ \text{m}^2} \times \frac{298\ \text{g}\ CO_2}{1\ \text{g}\ N_2O} \quad [5]$$

where x_1 is the average daily N_2O emission rate (g N per ha day^{-1}). For CH_4 the equation is similar but the mole ratio 44:28 for N_2O:N becomes 16:12 for CH_4:C and the GWP term for CH_4 (25) substitutes for N_2O's (298).

The energy used for field operations must also be determined, usually by standard tables to calculate annual diesel use, which is then converted into CO_2e.

$$CO_2e\ (\text{diesel}) = \frac{x_1\ \text{l}\ C_{16}H_{34}}{\text{ha} \times \text{year}} \times \frac{832\ \text{g}\ C_{16}H_{34}}{1\ \text{l}\ C_{16}H_{34}} \times \frac{192\ \text{g C}}{226\ \text{g}\ C_{16}H_{34}} \times \frac{44\ \text{g}\ CO_2}{12\ \text{g C}} \times \frac{1\ \text{ha}}{10^4\ \text{m}^2} \quad [6]$$

where x_1 is the average annual diesel use for the field. Likewise, the CO_2e costs of other agronomic inputs such as fertilizer and pesticides must be calculated on the basis of actual use and their embedded CO_2e costs (e.g., Gelfand *et al.*, 2013).

Annual SOC change is calculated as:

$$CO_2e\ (\text{SOC})\ \ \text{g}\ CO_2 \times \text{m}^{-2}\ \text{yr}^{-1} = \frac{(x_1 - x_2)\ \text{kg C}}{\text{m}^2 \times x_3\ \ \text{year}} \times \frac{44\ \text{kg}\ CO_2}{12\ \text{kg C}} \times \frac{10^3\ \text{g}\ CO_2}{1\ \text{kg}\ CO_2} \quad [7]$$

where x_1 is the current soil carbon content of the target system (in kg C per m^2), x_2 is the original soil carbon content, and x_3 is the period of carbon accumulation (the difference in years between current and original).

Once calculated, the overall balance for a given system can be tallied as in Table 2, which shows results of a GWI analysis

Table 2 Global warming impacts (GWIs) for four cropping systems and a field abandoned from agriculture and undergoing ecological succession[a]

Cropping System	*Soil C*	*N_2O*	*CH_4*	*Farming input*							*Net GWI*
				N	*P*	*K*	*Lime*	*Fuel*	*Seeds*	*Pesticides*	
				(g CO_2e per m^2 yr^{-1})							
C–S–W conventional	0 (31)	34 (6)	−0.8 (0.1)	32.7	0.4	1	3	13	7	7	98 (31)
C–S–W no-till	−122 (31)	35 (4)	−0.8 (0.1)	32.7	0.3	1	4	9	7	16	−18 (31)
Alfalfa	−122 (92)	33 (3)	−1.0 (0.1)	0	0.3	4	14	11	6	3	−52 (92)
Hybrid poplar	61 (153)	17 (3)	−0.8 (0.0)	3.3	0	0	0	1	0	2	84 (153)
Successional	−397 (31)	11 (1)	−1.1 (0.1)	0	0	0	0	0	0	0	−383 (31)

[a]GWIs are based on annual greenhouse gas emissions of cropping systems of the Kellogg Biological Station Long-term Ecological Research site in southwest Michigan, USA for the period 1989–2009. Values are means±SE (n=4–6 replicate blocks). C–S–W=corn–soybean–wheat rotation.

for five different cropping systems in Southwest Michigan, USA (Gelfand *et al.*, 2013). Here, for example, one can see that for a conventionally managed corn–soybean–wheat rotation the greatest GHG cost over a 20 year period was from N_2O emissions at 34 g CO_2e per m^2 yr^{-1}, followed closely by nitrogen fertilizer manufacture (33 g CO_2e per m^2 yr^{-1}). The cost of fuel, seeds, and pesticides summed to 27 g CO_2e per m^2 yr^{-1}, for a total cost of 98 g CO_2e per m^2 yr^{-1}. The no-till system, otherwise identical but for tillage, in contrast had a net cost of −20 g CO_2e per m^2 yr^{-1} – indicating net mitigation – on account of substantial soil carbon sequestration. Figure 5 provides a graphical illustration of the net balances: in the top part of the figure is the net GWI for each system broken out by component. The bottom graph shows clearly those systems that are net GHG sources versus net GHG mitigators.

Such a comparison has at least two purposes. First, one can identify the practices within each system that contribute the greatest GHG burden (or conversely, the least) and target mitigation efforts toward those practices with the greatest payout. Second, one can use such comparisons as a basis for crediting systems on a GHG market. If the conventional system is considered business as usual, the conversion of this system to another ought to generate carbon credits as the difference between business as usual and the alternative system. Converting to no-till, for example, would generate 118 g CO_2e credits per year on average, whereas retiring the land to successional vegetation would generate 481 CO_2e credits (see Table 2). If the products of these systems were used to generate biofuels, then the respective fossil fuel offset credits could be added in as well (Gelfand *et al.*, 2013) – assuming management changes do not create indirect carbon costs by displacing lost food production to lands newly converted to agriculture elsewhere (Searchinger *et al.*, 2008). This also assumes that net soil carbon gains are permanent.

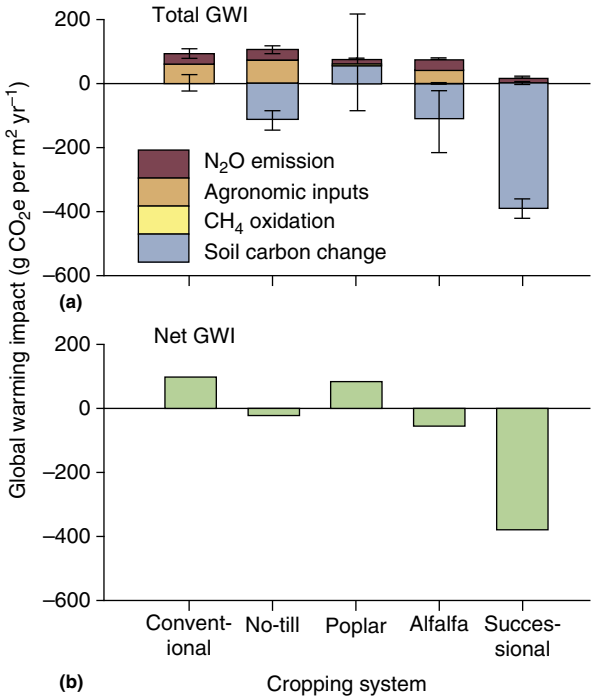

Figure 5 (a) Total and (b) net GWI for four cropping systems and a field abandoned from agriculture and undergoing ecological succession at the W.K. Kellogg Biological Station Long-term Ecological Research site in southwest Michigan, USA for a 20-year period ending in 2009. Conventional and no-till systems are corn-soybean-wheat rotations. Reproduced from Gelfand, I., Sahajpal, R., Zhang, X., *et al.*, 2013. Sustainable bioenergy production from marginal lands in the US Midwest. Nature 493, 514–517.

Not yet included in these analyses is the GWI of changes in NO_x fluxes. This is because of spatial variability in the regional conversion of NO_x to tropospheric ozone and the complexity of ozone's subsequent effect on radiative forcing. The short lifetime of ozone in the atmosphere (hours to days) precludes the calculation of a meaningful GWP for ozone (IPCC, 2007).

This type of systems approach is crucial for fully evaluating the total GHG effects of different agricultural practices. Otherwise it is difficult to know, for example, that the additional herbicides needed for no-till offset the fuel savings or carbon sequestration relative to conventional practices (Table 2). These sorts of trade-offs must be evaluated at the systems level.

Future Mitigation Potentials via Soil Management: Cropping Systems and Biofuels

Our current understanding of agriculture's impact on the atmosphere's GHG burden reveals many opportunities for mitigation, almost none of which have been implemented to date. Designing effective mitigation practices for soil management requires a systems approach because some practices are incompatible with one another and others involve trade offs. The CO_2e costs of each consequence must be evaluated, in turn, to show that no-till management does, indeed, provide a net GWI benefit, i.e., net mitigation (see Figure 5).

The design of future climate-benefiting systems can be best informed by existing whole-system studies (e.g., Robertson *et al.*, 2000; Robertson and Grace, 2004; Mosier *et al.*, 2005, 2006; Adviento-Borbe *et al.*, 2007; Piva *et al.*, 2012; Sainju *et al.*, 2012; Ma *et al.*, 2013). A number of mitigation practices can be implemented to significantly reduce GHG emissions from agricultural soils. Among those most important across most types of annual cropping systems are:

- more precise fertilizer nitrogen management to reduce N_2O emissions;
- permanent no-till management to maximize soil carbon gain and reduce fuel use;
- irrigation management to minimize the need for electricity and fuel to pump water;
- leguminous cover crops to maximize soil carbon gain and reduce the need for synthetic nitrogen fertilizers; and
- diverse rotations that include perennial crops such as alfalfa and high-biomass crops such as corn to build soil carbon and reduce the need for pesticides.

Many of these practices can be combined such that it is possible to not just reduce cropping system GHG costs to nil but to make the system net negative, thereby providing a valuable ecosystem service beyond the farm boundary.

An additional, emerging mitigation opportunity is cellulosic biofuels (Perlack *et al.*, 2005; Robertson *et al.*, 2008). Biofuels made from cellulosic feedstocks – crop residues and purpose-grown lignocellulose biomass – can offset fossil fuel use and thereby provide a climate benefit substantially greater than that of the cropping system itself (NRC, 2009; Gelfand *et al.*, 2013).

The environmental hazards of grain-based biofuels are well known (Crutzen *et al.*, 2008; Donner and Kucharik, 2008; Landis *et al.*, 2008; Robertson *et al.*, 2011) and can be largely avoided by the use of perennial feedstocks that require little soil disturbance after planting but for harvest and perhaps fertilizer applications. Perennial cellulosic feedstocks use little fossil fuel to plant and maintain, require few inputs, and have a correspondingly high energy return on investment (Farrell *et al.*, 2006), which can translate into high climate benefit.

However, the climate benefits of biofuels are conditional. First, the CO_2 captured and used to offset fossil fuel use must be greater than the CO_2e costs of establishment (Fargione *et al.*, 2008), which can create a so-called carbon debt that can take decades to a century or more to repay (Gelfand *et al.*, 2011). Almost all of this debt is related to soil processes. Second, the establishment of a new biofuel crop must not result in the creation of new cropland elsewhere to replace food production that was displaced by the new biofuel crop (Searchinger *et al.*, 2008). Indirect land use change with its associated soil- and vegetation-related GHG costs can discount a substantial fraction of the local crop's CO_2e benefit (Plevin and Kammen, 2013). And third, the CO_2e benefit of the new crop must be discounted by the expected CO_2e benefit of the existing ecosystem (Searchinger *et al.*, 2009). For example, a growing forest sequesters substantial carbon in its soil and biomass. To achieve a climate benefit, the carbon capture of a replacement crop must exceed both the current and future expected rate of carbon capture by the forest vegetation and soil (Field *et al.*, 2008). Soil carbon storage and fluxes of N_2O and CH_4 play a large role in the GHG balance of biofuel cropping systems.

Worth noting overall is that although soil GHG emissions from agriculture can be substantial, and are the single greatest contributors to the GHG footprint of agriculture, emissions can be managed. Purposeful changes to cropping practices and careful consideration of their GHG impacts can substantially reduce and even reverse their climate impacts.

Ammonification Release of ammonium from organic forms of N by soil organisms.
Chemodenitrification Chemical reaction between high concentrations of nitrite at alkaline soil pH which results in losses of gaseous forms of N.
Denitrification Microbe-induced losses of gaseous forms of N from nitrate under low soil concentrations of oxygen.
Eutrophication Low concentrations of oxygen in aquatic environments that result from the decay of dense algal growth induced by an abundant supply of nutrients.
Immobilization Incorporation of nutrients during growth by soil microbes.
Macronutrients Nutrients that are required in large amounts to support plant growth.
Micronutrients Nutrients that are required in very small amounts to support plant growth.
Mineralization Microbe-mediated release of inorganic nutrients from organic matter.
Nitrification Conversion of ammonium to nitrite and nitrate by soil organisms.
Symbioses Mutually beneficial relationships between microorganisms and plants.

Introduction

Nutrients Required by Plants

Some soil nutrients such as nitrogen (N), phosphorus (P), potassium (K), sulfur (S), magnesium (Mg), and calcium (Ca) are key components of organic compounds in plants, such as proteins and nucleic acids, or contribute to the internal control of cellular pH and osmotic potential. These elements are collectively described as macronutrients. Micronutrients such as molybdenum (Mo), iron (Fe), and zinc (Zn) are constituents of enzymes and are thus required by plants in very small amounts. Although the concentrations of macro- and micronutrients detected in plant shoots can vary considerably depending on plant species, plant age and stage of development and the general differences in function between macro- and micronutrients are usually reflected in the average concentrations of mineral nutrients observed in actively growing plants (Table 1).

Table 1 Example of concentrations of mineral nutrients detected in plant shoot dry matter

Element	*Symbol*	*%*	*mg kg^{-1} (ppm)*
Nitrogen	N	1.5	15 000
Potassium	K	1.0	10 000
Calcium	Ca	0.5	5 000
Magnesium	Mg	0.2	2 000
Phosphorus	P	0.2	2 000
Sulfur	S	0.1	1 000
Chloride	Cl	0.01	100
Iron	Fe	0.01	100
Manganese	Mn	0.005	50
Zinc	Zn	0.002	20
Boron	B	0.002	20
Copper	Cu	0.000 6	6
Molybdenum	Mo	0.000 01	0.1

Sources of Plant Nutrients

Many nutrients present in soil originate from weathering of the parent rock through the action of water, acidity, and frost. Much of the soil N, however, would originally have been derived from biological N_2 fixation (see the N cycle section). However, regardless of their origin, large amounts of nutrients are often present in soil organic matter, which includes both the active (labile) fractions associated with the microbial biomass, or fresh and partially decomposed plant and animal residues having turnover times in the order of months to years, and the more stable forms such as humus, which can take decades to turnover. Approximately 90–95% of the soil N, 40% of the soil P, and 90% of the soil S can be present in soil organic matter, which typically has a carbon (C):N:P:S ratio of 100:8:2:1.4 (Kirkby *et al.*, 2011). In agricultural soils, approximately 2% of the nutrients in soil organic matter are made available to plants each year as a result of microbe-mediated mineralization processes and this provides a significant source of macronutrients such as N and S to satisfy plant requirements. In the case of P, its availability to plants is more commonly controlled by soil chemistry and chemical transformations, although soil organic matter can also be an important source of P for plant uptake in certain circumstances.

The Influence of Water on Nutrient Availability and Uptake

Water is a key factor that influences nutrient availability for plants. Soil water content is an important determinant of microbial activity, which can have either positive or negative implications for the cycling of nutrients and/or in influencing the plant's capacity to capture and utilize nutrients (Table 2). Microbial activity and the release of nutrients tend to be greatest in warm soil when it is near field capacity (i.e., the water content of soil a few days after rain has saturated the soil and free drainage has ceased). As soils dry, microbial activity also declines and nutrient release from organic matter slows.

Table 2 Examples of interactions between soil biology and plants that can affect either availability of nutrients from soil or the capacity of plants to capture or utilize nutrients

Positive	*Negative*
Inputs of N via symbiotic and free-living N_2 fixation.	N losses via denitrification in waterlogged soils.
Microbe-mediated release (mineralization) of nutrients from soil and plant organic matter.	Incorporation (immobilization) of nutrients during growth by the soil microbial biomass.
Phosphate solubilization increasing P availability.	Direct competition with plants for available forms of nutrients.
Mycorrhizal enhancement of P and Zn uptake by plants.	
Plant growth-promoting bacteria and disease-suppressive organisms enhancing plant growth potential.	Deleterious bacteria, root pathogens, and pests impacting on root vigor, plant health, and growth potential.
Biochelation of toxic materials.	Release of phytotoxic metabolites.

At the other extreme, nutrient loss processes generally prevail if soils become waterlogged and air is displaced from soil pore spaces by water so that soil oxygen levels become exceptionally low (Peoples *et al.*, 2009b).

Water is also the medium by which nutrients move through the soil to plant roots. Soluble and abundant nutrients such as N, Ca, Mg, and S are transported to the root surface by mass flow, whereby nutrients move with the water flow as the plant roots absorb water for transpiration. Micronutrients, P, and K, which are often present in low concentrations in soil solution, however, tend to be supplied to plant roots by diffusion as they move from areas of high concentration in soil to areas of low concentration in the plant rhizosphere. Plant nutrients are usually most readily available when the soil is near field capacity. Soil water is held as a film around soil particles; the thickness of this film of water decreases and the water becomes progressively more difficult for plant roots to extract as the soil water content declines under dryland (rainfed) conditions. Consequently, nutrient availability will be lowest when the soil water content approaches permanent wilting point when plant roots can no longer extract water from the soil. As the soil water content diminishes, diffusion path lengths in the thin film of water around soil particles become longer, thus slowing the rate of nutrient supply to roots. Some less-soluble nutrients may precipitate out of the soil solution and become unavailable to plants. However, these minerals will dissolve and become available again as the soil is rewetted. Changes in redox potential under waterlogged conditions can result in toxic levels of Mn accumulating in soil. The reduction of sulfate ($SO4^{-}$) to hydrogen sulfide (H_2S) under prolonged periods of waterlogging also decreases the solubility of Fe, Zn, and other heavy metals, which can result in deficiency symptoms in plants (Marschner, 1986).

Nutrient Cycling

The subsequent discussion on aspects of nutrient cycling will focus on just N and P. The availability of either of these two particular macronutrients frequently constrains plant productivity, but they differ markedly in cycling processes in the soil. The following will describe how N and P is added (inputs) to terrestrial ecosystems and then either cycled through or removed (losses) from the soil–plant–animal continuum.

The Nitrogen Cycle

The N cycle comprises soil, plant, and animal pools that contain relatively small quantities of biologically active N, in comparison with the large pools of relatively inert N in the lithosphere and atmosphere. Despite their small size, these active pools exert a substantial influence on the global biogeochemical N cycle. After C (~40% of plant dry matter) and oxygen (O,~45%), N is the next most abundant element in plants, commonly representing 1–2% of the plant dry weight in grasses and forbs, 2–3% in legumes, and ≤0.5% in woody tissue and ≤2% in leaves of woody perennials. The N concentrations of plant roots have been less intensively investigated than shoots but are typically at the lower end of the range recorded for the above-ground components of the species.

Nitrogen is a key component of plant amino and nucleic acids as well as chlorophyll and provides the basis for the dietary N (protein) of all animals including humans. The total amounts of N taken up by plants are a reflection of ecosystem productivity and N supply. For example, the N uptake by irrigated cereals in highly productive agricultural systems may be as much as 450 kg N ha^{-1} per year, whereas in low rainfall (<300 mm per annum) environments, crop N uptake is generally <100 kg N ha^{-1}. The major food crops grown for human consumption, for example, wheat, maize, and rice require 20, 15, and 12 kg N, respectively, for every Mg (tonne, 10^6 g) of grain harvested. Grain generally represents >50% of the above-ground plant N and equates to the global removal of approximately 31 Tg N (million tonnes; 10^{12} g) from soil each year in these three cereal crops alone (Peoples *et al.*, 2009b). By contrast, most of the N in plant material in pasture and forestry ecosystems eventually returns to the soil surface as litter (in the absence of fire) or via excreta from grazing animals. Although there is considerable information on above-ground fluxes of plant N, there is a paucity of data for N accumulated in roots, and thus it is difficult to accurately quantify total returns of N to soil as plant residues (McNeill and Unkovich, 2007).

Nitrogen cycling occurs via the decomposition of organic matter in soil, which provides available forms of N for plant and microbial uptake. Nitrogen subsequently returns to the soil organic N pool following death or via dung or urine from grazing animals (**Figure 1**). Decomposition of organic matter is mediated by the microbial biomass, which, despite being a very small component within soil organic matter, is a critical

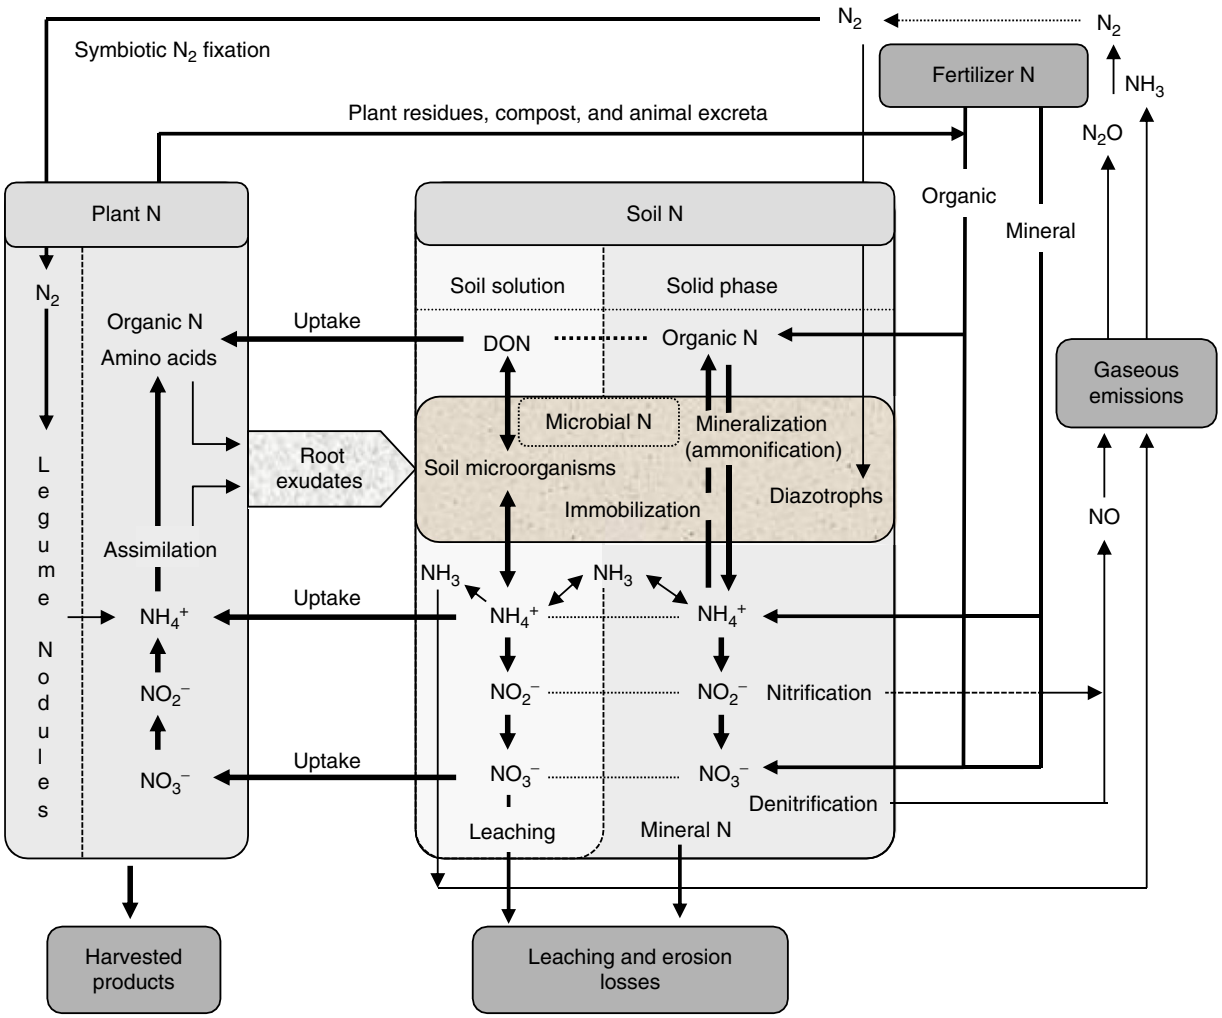

Figure 1 Schematic representation of the soil–plant N cycle showing major pools of N, points of input and output, and major transformation pathways (DON, dissolved organic N).

nutrient pool, with the living microbial biomass providing the enzymes for decomposition of organic matter, whereas the dead microbial biomass represents a labile pool of soil N for mineralization.

Nitrogen inputs

Atmospheric N deposition

Nitrogen inputs through deposition of dust (dry deposition) or in rain (wet deposition) are often overlooked. The relative importance of dust or N contained in rainfall depends on the extent of climatic conditions and atmospheric pollution. Organic N deposition, in the form of amine aerosols, organic nitrates, and particulate N (dust, pollen, and bacteria) in the atmosphere, can make up ~30% of N inputs in some ecosystems. Ammonia (NH_3) released to the atmosphere tends to return to the plant–soil system relatively rapidly either redeposited near the source of emission or, because it is highly water soluble, dissolved in atmospheric water. Nitrous oxides can return to terrestrial ecosystems as nitric acid (HNO3; acid rain), which has serious implications for soil and atmospheric chemistry (Mosier, 2001).

Deposition tends to be greatest adjacent to urban and industrial areas but can be particularly high in areas surrounding livestock production facilities. For example, NH_3 evolved from a cattle feedlot provided the equivalent of 50 kg N ha^{-1} to soils within a few km of the feedlot (Mosier, 2001). The annual contribution of deposited N to cereal crops in the UK has been reported to be in the order of 20–45 kg N ha^{-1}, but elsewhere in the world where inputs of N to the atmosphere from intensive livestock facilities and industry are smaller, and where rainfall and ecosystem productivity are lower, deposition is predominantly as dust and rates are more likely to be <5 kg N ha^{-1} per year (McNeill and Unkovich, 2007). Terrestrial atmospheric N deposition has been estimated to be 20–23 Tg N annually, approximately half of this occurring on agricultural lands, with a further 16 Tg N being deposited in oceans (Mosier, 2001; Smil, 2001).

Biological N_2 fixation

Although dinitrogen gas (N_2) represents almost 80% of the earth's atmosphere, it is not a source of N that is readily available to plants. However, a number of procaryotic

microorganisms utilize the enzyme nitrogenase to reduce atmospheric N_2 to NH_3, which is subsequently converted into amino acids or other forms of N to be used to support their growth. Biological N_2 fixation by some diazotrophs can occur in a free-living state. This includes the photosynthetic cyanobacteria (previously known as blue-green algae) and a number of species of bacteria that rely on decomposition of plant residues as an energy source. Other N_2-fixing microbes require habitats abundant in C and tend to fix N_2 in various associations with plants. The diversity of types of N_2 fixation have arisen from the multiple modes with which bacteria and eukaryotes have coevolved to meet the rather exacting demands of active N_2 fixation. Relationships between prokaryotes and plants range from rather loose associations of free-living heterotrophic bacteria with plant roots or endophytic N_2-fixing bacteria present in the vascular tissues of C_4-photosynthetic pathway graminaceous plants such as sugarcane, to highly evolved symbioses that involve complex morphological differentiation of both microbe and plant in specialized root structures such as nodules. Symbioses between N_2-fixing bacteria and eukaryotes include: (a) Cyanobacteria with fungi in lichens, cycads, and *Gunnera*; (b) Actinomycetes (generally placed in the genus *Frankia*) with a range of angiosperms such as Alders and Casuarinas; and (c) the soil bacteria, rhizobia, with legumes (and a single nonlegume genus *Parasponia*).

There is quantitative evidence that indicates that nonsymbiotic diazotrophs have the potential to provide a useful source of N for agricultural production in some tropical and subtropical environments, but a number of researchers argue that annual inputs of fixed N from such sources are more likely to be <5–10 kg N ha^{-1} in temperate agriculture (Unkovich and Baldock, 2008). Although N_2 fixation by a legume–rhizobia symbiosis in any particular farming system can be greatly influenced by specific management practices and a range of abiotic or biotic stresses, the amounts fixed are generally closely related to legume biomass production. Measures of N_2 fixation for legumes from around the world suggest that N inputs can often be in the order of 100–200 kg shoot-N per year or growing season for both crop and forage legumes (Carlsson and Huss-Danell, 2003; Peoples *et al.*, 2009a).

Although calculations of global inputs of fixed N are subject to gross approximations, estimates suggest that crop legumes such as soybean, peanut, common bean and field peas, and forage legumes such as alfalfa (lucerne) and clovers could all be contributing between 33 and 46 Tg of N each year to agriculture, with the combined contributions from free-living N_2-fixing bacteria and endophytic, associative, and other nonlegume symbiotic relationships providing a further 17–24 Tg N fixed (Herridge *et al.*, 2008).

Fertilizer N

Before the advent of N fertilizers, 25–50% of a farm was typically maintained in a legume-rich pasture or cover crop, and it has been estimated that in some farming systems in the 1950s, as much as 50% of all available N may have originated directly from leguminous food, forage, and green manure crops. However, most farmers around the world progressively replaced legume rotations and organic sources of N fertility with synthetic N fertilizers over the following 3–4 decades, so that by the end of the twentieth century the US agriculture derived almost half of its total N supply from fertilizers and two-thirds of all N in China's food originated from the industrial synthesis of NH_3 by the energy-intensive Haber–Bosch process (Smil, 2001). The rapid adoption of N fertilizers occurred in parallel with the increasing availability of fossil energy, and annual global fertilizer consumption increased from 11 Tg N in 1960 to 80 Tg N in the 1990s and has remained between 80 and 100 Tg N ever since. Urea is the most widely used form of N fertilizer applied in agriculture and represented 67% of total fertilizer N consumed in 2007 (Peoples *et al.*, 2009b). Average rates of N fertilizer applied by farmers vary widely across geographic region and crop and can range from 30 to 250 kg N ha^{-1} (Smil, 2001).

Nitrogen returns via grazing livestock

Grazing animals exert substantial direct influence on N cycling through their return of ingested N in plant material to the soil in highly concentrated patches as urine and dung, thus providing nutrient-rich sites which can have positive and negative influences on subsequent plant growth and other N cycle processes. Indirect effects of grazing on the N cycle can also occur as plants are defoliated, changing their internal N economies and N dynamics in the rhizosphere, as well as impacting on plant community structure. Of the dietary N consumed by domestic livestock, $<30\%$ is retained as live weight gain, milk, or wool, with the remainder being excreted. Annual returns of excreta from grazing animals can represent from 130 to 240 kg N ha^{-1} for steers or sheep grazing clover/grass pastures to 300–450 kg N ha^{-1} for dairy herds on heavily N-fertilized grasslands. Urinary N constitutes between 40% and 80% of the total N excreted and increases with increasing concentrations of N in the diet. Urine is deposited in localized areas of pasture at rates equivalent to 100–500 kg N ha^{-1} and 600–1200 kg N ha^{-1} for sheep and cattle, respectively (Ledgard, 2001).

Nitrogen transformations in soil

The largest N pool in the plant root zone is in the soil organic matter, but this is mostly unavailable to plants. Decomposition of organic matter is a complex process that occurs, to differing extents, with a continuum of organic materials of varying ages, stages of decay, and degrees of recalcitrance that includes newly added plant residues (above and below ground), animal waste products, root exudates, and rhizodeposits as well as various existing or 'native' soil organic matter pools.

The process of microbial decomposition and ammonification of organic N into available inorganic forms commences with the breakdown of organic compounds to provide the soil microbes with a C source for respiration and growth (Fillery, 2001). Much of the simple organic N released is rapidly assimilated (immobilized) by the soil microbial population. Mineral N for uptake by plants becomes available when the amounts of N released from the organic residues exceed the microbial requirement for N for growth (i.e., when ammonification of N exceeds microbial immobilization processes). This is more likely to occur with leguminous material than with the residues of cereals or grasses because legume organic matter has a higher N content and lower C:N ratio.

Field data collected from rainfed systems suggest that peak rates of ammonification of organic matter of approximately 1 kg N ha^{-1} per day can occur in spring or summer when both soil water and temperatures are favorable for microbial activity. Rates of ammonification are considerably reduced in winter due to low temperatures and essentially fall to zero in a dry soil. Ammonification processes are known to be very responsive to rainfall, particularly when a seasonally dry soil is rewet (e.g., Sparling *et al.*, 1995). Collectively, the experimental data indicate that between 0.1 and 0.9 kg N ha^{-1} can be accumulated in the soil profile per millimeter rainfall, depending on the timing and the amount of rainfall, previous cropping history, the relative water-holding capacity of the soil, and its susceptibility to leaching losses. The wide diversity of organisms in soil that use organic C as an energy source minimizes the effect of soil pH on rates of ammonification of organic N.

During the ammonification process, released ammonium (NH_4^+) is typically used as an energy source by two distinct groups of soil organisms. It has been long understood that a small group of bacteria, with the majority belonging to the betaproteobacteria, oxidizes NH_3 to produce nitrite (NO_2^-; Paul and Clark, 1996). The recent discovery that Archaea have the genetic material to produce NH_3 monooxygenase, the enzyme responsible for catalyzing the conversion of NH_3 to NO_2^-, implies that Archaea also nitrify (Schauss *et al.*, 2009). Evidence is accumulating that shows that nitrifying Archaea are widespread in soil and in many soils are numerically more dominant than bacterial nitrifiers. Nitrite N produced by ammonia oxidizers is, in turn, converted into nitrate (NO_3^-) by nitrite-oxidizing bacteria (Paul and Clark, 1996). Both ammonium and nitrate can be used for growth, but plants generally prefer nitrate.

Soil pH through its effect on the concentration of NH_3, the substrate for ammonia oxidizers, has a major effect on the conversion of ammonium to nitrate by nitrifying bacteria, with little activity below pH 4, optimum activity at slightly acidic to neutral pH, and evidence of a decline in activity above pH 8 (Paul and Clark, 1996). In contrast, Archeal nitrifiers appear to be favored over bacterial nitifiers at lower soil pH (O'Sullivan *et al.*, 2011) and at alkaline soil pH (Shen *et al.*, 2008), suggesting that Archaea nitrifiers may be better adapted to extremes in soil pH than bacterial nitrifers. Evidence is mixed as to whether Archaea have a higher affinity for low NH_3, a trait that would enable Archaea to operate more effectively, at least at low soil pH.

Once urea, either applied as fertilizer or excreted in urine by animals, comes in contact with soil, it is rapidly hydrolyzed to CO_2 and NH_3 by the enzyme urease. NH_3, in turn, is oxidized and nitrified to NH_4^+ and NO_3^- as described above. The addition of alkalinity during the hydrolysis of urine and urea fertilizer increases soil pH in the zone of placement with the increase in pH dependent on rate of N application and soil pH buffering capacity. Where alkaline soil pH results, losses of NH_3 can occur from soil zones in contact with urea granules and from urine patches (Thompson and Fillery, 1998).

Plant utilization of nitrogen

Plant roots assimilate available forms of N from the soil either released directly from N fertilizers or arising from N mineralized from (a) soil organic matter, (b) plant residues, or (c) animal urine or feces. Legumes have an added capacity of accessing atmospheric N_2 for growth through symbiotic relationships with soil bacteria (see biological N_2 fixation section).

The soil layers explored by crop roots commonly contain between 5000 and 12 000 kg of soil organic N per hectare. Approximately 2% of this is typically mineralized each year. As the conversion of organic N in plant residues into inorganic N is dependent on microbial activity, only a portion of the N contributed to soil by legumes or other plant material will become available for root uptake in the short term. A number of studies indicate that generally $<30\%$ of the legume N is directly taken up by a subsequent crop (Peoples *et al.*, 2009a). The low recovery of legume N (10–15% on average) is usually much lower than uptake of fertilizer N (30–40% average recovery of the N applied depending on the form of fertilizer used, crop, and farming system; Crews and Peoples, 2005). A notable feature of legume residues is that, although a lower proportion of the legume N is recovered by a subsequent crop than from fertilizer, less legume N tends to be lost through leaching or denitrification than from fertilizer N, so that considerably more legume N remains in the soil system at the end of the growing season (on average, 60% of the applied legume N) compared with fertilizer sources (30%; Crews and Peoples, 2005). After a period of time, the subsequent rate of mineralization of the legume N remaining in soil can be quite slow, so that the legume N that was not mineralized during the first cropping season becomes available only very slowly thereafter for successive crops (usually $<10\%$ per year). Consequently, one of the main contributions of legumes is in the maintenance of the long-term organic fertility of the soil (Fillery, 2001).

The high localized level of N excreted by grazing animals can suppress N_2 fixation by legumes in the immediate vicinity of the urine patch (Ledgard, 2001) but stimulates the growth of surrounding grasses and may provide a small contribution of N to following crops (Thompson and Fillery, 1998).

Factors that contribute to N loss processes

Nitrogen can be lost from soil through wind or water erosion, runoff, leaching of nitrate or dissolved forms of organic N, or via gaseous releases to the atmosphere in (a) the form of NH_3 as the result of volatilization from ammonia-based fertilizers and animal urine patches; (b) nitrous oxide (N_2O) and other nitrogen oxides (NO and NO_2) released during nitrification; and (c) the same nitrogen oxides and N_2 as the result of denitrification (**Figure 1**).

The amount of ammonium N in soil at the interface with the atmosphere, specifically the concentration of NH_3 in soil solution, determines the potential for NH_3 loss. It is accepted that NH_3 loss only occurs from alkaline soil. In the case of urea-based fertilizer, anhydrous NH_3 and animal urine, soil pH increases after N application. The extent of pH change is dependent on the soil pH buffering capacity, which is largely determined by soil texture. Other factors influencing NH_3 loss include soil temperature, soil water content, wind speed, and the presence of a plant canopy. In contrast to other mechanisms of N loss, NH_3 emissions typically occur 7–14 days after fertilizer application or urine deposition. Small rainfall events can increase NH_3 loss from urea-based fertilizers and

urine by increasing the activity of the urease enzyme that mediates hydrolysis. Large rainfall events or irrigation that moves ammonium N into the soil reduces the potential for NH_3 loss (Sommer *et al.*, 2004).

Denitrification occurs when a soil has restricted supply of oxygen which triggers microbial use of nitrate, nitrite, and nitrogen oxides as terminal electron acceptors in place of oxygen. Extensive knowledge of the denitrification process exists, including the diversity of microorganisms that denitrify, the biochemical pathways linked to each step in the reduction chain between nitrate and N_2 gas, substrate kinetics, and soil and environmental factors that impact on rate of denitrification, with most of this information derived from controlled environment studies (see Aulakh *et al.*, 1992 for a review of early literature). The classical view of denitrification is that nitrate is first reduced to nitrite and subsequently to nitric oxide, then to N_2O, and finally to N_2 gas. However, intermediate products of denitrification can react with other N constituents, for example, one atom from NO or N_2O can combine with one atom of another N-containing source, resulting in two molecules of N_2O being produced for every nitrate molecule reduced in a process termed codenitrification (Baggs, 2011). Nitrite in high concentration at alkaline soil pH can react chemically to produce gaseous N compounds in a process termed chemodenitrifcation (Chalk and Smith, 1983). In this case, inhibition of nitrite oxidation, but not NH_3 oxidation during nitrification, results in accumulation of nitrite, as observed after band application of urea or anhydrous NH_3. Percentage water-filled pore space (WFPS) in soil, quantities of readily respirable carbon, soil temperature, and the supply of nitrate are key factors that determine amounts of N that are denitrified.

It has been known for some time that N_2O is released during the process of nitrification. Recent work indicates that betaproteobacteria ammonia oxidizers can also produce N_2O in periods of oxygen limitation in the denitrification process (Baggs, 2011). Percentage WFPS in soil appears to be a key driver as to whether nitrification or denitrification are the key sources of N_2O with denitrification the major contributor at 70% WFPS and nitrification the key source when soil is kept between 35% and 60% WFPS in a silt loam (Bateman and Baggs, 2005).

Managing denitrification in soil and other man-made environments has assumed prominence in recent decades largely to reduce the release of N_2O, NO, and NO_2, which are directly or indirectly linked to global warming (Mosier *et al.*, 2002). However, the proportion released as N_2O is typically small in comparison with the portion released as N_2 gas. This conversion of nitrate into the environmentally harmless N_2 gas represents reduced efficiency of utilization of applied or plant-available N. The need to apply fertilizer N produced in energy-consumptive industries to overcome N deficiencies caused by denitrification impacts on the C-footprint for agriculture, highlighting the need for strategies for minimizing denitrification (Mosier *et al.*, 2002).

Leaching of nitrate is dependent on transport of water through soil and the concentration of nitrate in soil solution and typically occurs when water inputs into the soil system exceed short-term evapotranspiration demands (Fillery, 1999). Leaching of nitrate is more prevalent in sandy-textured soils that have higher hydraulic conductivity than in loams or clays. Strategies for reducing nitrate leaching are discussed in detail by Meisinger and Degado (2002).

Table 3 provides a summary of the complexity of factors involved in these various N loss processes. The influencing factors can be divided into environmental variables, which are largely uncontrollable, and the impacts of human activity where there is some ability to manage losses. The relative importance of the different loss processes will vary considerably across different regions based on climate, soils, dominant land use, and the amount and source of N applied (Peoples *et al.*, 2009b). One of the main factors that influence both the efficiency of N use and the extent of N losses is the degree to which the rates of supply of mineral N match rates of plant N requirements. This will be true regardless of whether the mineral N originated from fertilizer or organic sources. High rates of localized N applications in animal urine patches in pastures are one example where concentrations of mineral N are more likely to exceed plant need and to result in volatile or leaching losses of N. Indeed, it has been calculated that almost 75% of the NH_3 emitted from Western Europe might be derived from livestock compared with just 12% from fertilizer applications (Mosier, 2001).

It is when N supply (via fertilizer applications or mineralization of plant and soil organic matter) exceeds plant demand for N that there is the potential for mineral N to accumulate in soils and there is a risk of losses of N from the system (**Figure 1**; Crews and Peoples, 2005). Maintaining N in the ammonium form in soil can be a key management strategy to improve efficiency of use of applied N. Nitrification inhibitors have been developed and some marketed as soil amendments to control the process of nitrification. These consistently retard nitrification when tested under controlled environments in laboratories. However, the effectiveness of commercial nitrification inhibitors is less apparent when examined under field conditions for a range of crops (Wolt, 2004). Microbial degradation of nitrification inhibitors in soil along with displacement from the zone of fertilizer placement are explanations for the indifferent performance of nitrification inhibitors under field conditions. The uncertain return from investment together with high input cost has discouraged the use of commercial inhibitors in broad-scale agriculture. The recent demonstration that a tropical grass, *Brachiaria humidicol*a, releases compounds from roots that reduce the activity of nitrifying bacteria, the so-called biological nitrification inhibition, offers a less costly approach to managing nitrification if the same function can be introduced into important food crops and pasture species (Fillery, 2007).

The extent of annual global losses of N from soils has been calculated to be 20 Tg N via erosion and 17 Tg N in leaching (Smil, 2001), 11–31 Tg N as NH_3 from animal excreta and fertilizer, 6–8 Tg N as N_2O, NO, and NO_2, and 14 Tg N as N_2 (Mosier, 2001); however, there are large uncertainties around these estimates. All these different forms for N loss, with the important exception of N_2, either have important implications for human health or contribute to one or more of the many contemporary environmental problems associated with the increased N availability in the biosphere (Peoples *et al.*, 2009b). However, it should be acknowledged that a portion of

(Eds.), Nitrogen Fixation in Crop Production, Agronomy Monograph, vol. 52. Madison: American Society of Agronomy, Crop Science Society of America, Soil Science Society of America, pp. 349–385.

the volatile losses will be ultimately redeposited on soil to reenter the terrestrial N cycle (Mosier, 2001).

The Phosphorus Cycle

Phosphorus is an essential nutrient for plant growth and cellular function and typically constitutes between 2 and 5 g P kg^{-1} of tissue dry weight in agricultural plants. It is required for the structure and function of nucleic acids, integrity of lipid membranes, and for the maintenance of cellular energy systems. For animals, P is also an important component of teeth and bones. The P concentration of a mature sheep or cow is approximately 7–8 g P kg^{-1} of liveweight; approximately 80% of the P is found in the skeleton and teeth.

Most topsoils contain a large amount of total P (range: 0.2–3 g P kg^{-1} soil; Harrison, 1987) in both organic and inorganic P forms (**Figure 2**). By comparison, annual crop requirements and fertilizer inputs are typically only approximately 10–30 kg P ha^{-1} per year (i.e., approximately equivalent to adding only 8–24 mg of P kg^{-1} soil to the top 10 cm of the soil profile). Crop and pasture plants take up P from soil in the form of orthophosphate (HPO_4^{2-} and $H_2PO_4^{1-}$) via their roots.

Plants are responsive to P supply from soil and adapt their root systems to enable better exploration of soil when P is in low supply. Internally, P is also recycled from older and senescing leaves to functionally active tissues. Herbivores normally obtain their P by consuming plants (omnivores by consuming plants and animals and carnivores by consuming other animals). The supply of P is particularly important for growing animals because they accumulate P in muscle and bones and for lactating animals because they excrete relatively large amounts of P in milk. By contrast, nonlactating, mature animals do not accumulate P and will excrete P in feces and urine in amounts equivalent to the amount they consume. P is often one of the primary nutrient limitations for plant growth on farms and when this is the case, soil P levels can be increased by application of P fertilizers to increase plant production. In agriculture practiced on very low P soils and where fertilizer use is unaffordable or unprofitable, P can also be a primary limitation for animal production. This is more likely to be the case only at particular times of the year because energy and other nutrients are also limiting constraints in these systems. On farms, P is most often returned to soil in both inorganic (orthophosphate) and organic P forms as feces, urine, and as dead or trampled plant material. Phosphorus is also returned as a consequence of animal death. Organic P is hydrolyzed by soil microorganisms, and P entering the soil by this route is ultimately released as orthophosphate, the form that plants can access.

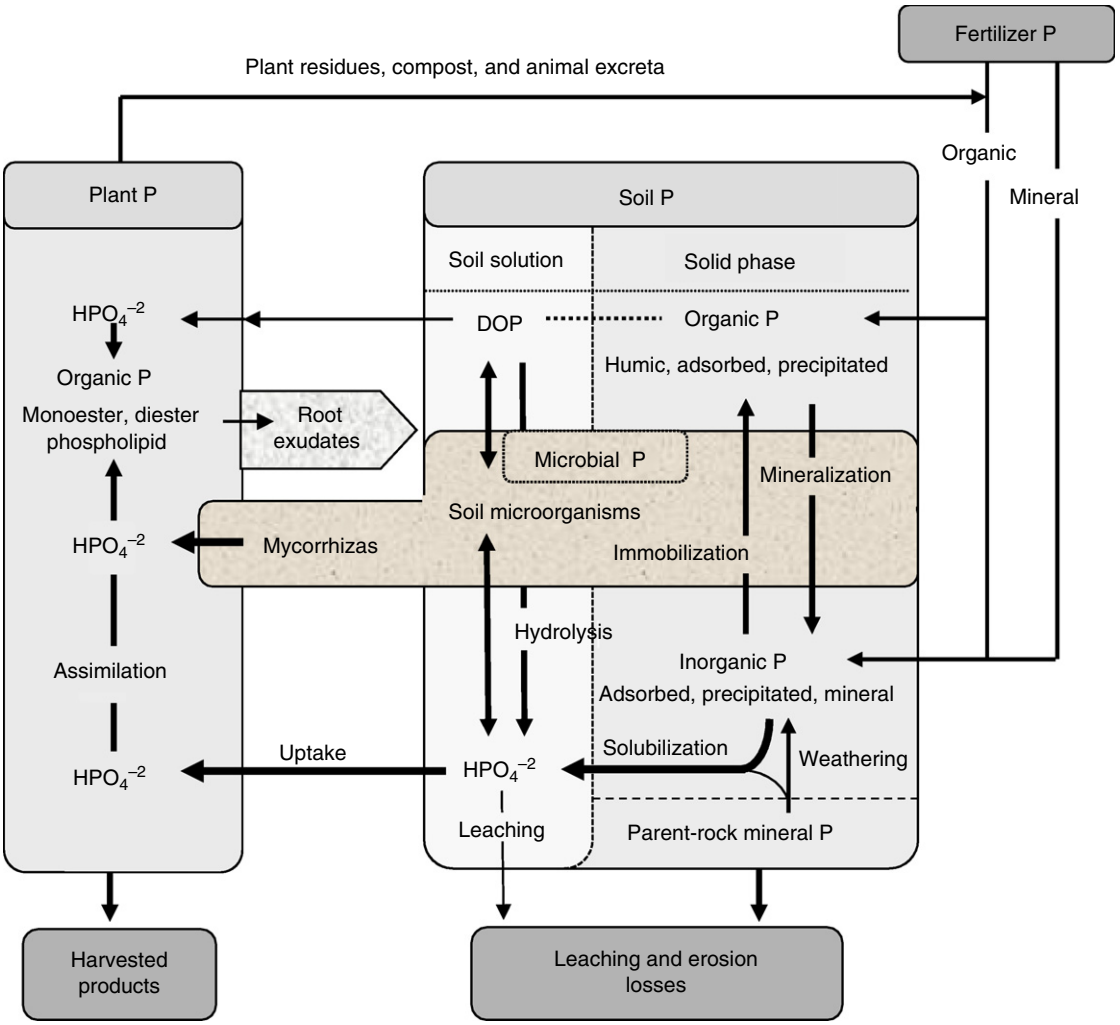

Figure 2 Schematic representation of the soil–plant P cycle showing major pools of P, points of input and output, and major transformation pathways (DOP, dissolved organic P).

Human interventions in the P cycle have significant impacts. Nutrient foraging is often practiced in subsistence and organic-based agriculture. P is collected in the form of waste materials and excreta from animals grazing over large areas and is applied to crops on a smaller area to enhance soil P availability and crop yields. In modern intensive agriculture, excreta combined with fertilizers derived from mined phosphate rocks are used to improve soil P availability and crop yields. A significant proportion of the inorganic and organic P in soil is slowly converted into sparingly available forms of inorganic and organic P, which constitute the majority of the reserve of total P that exist in soils. Relatively small proportions of total soil P are lost continually from the terrestrial landscape to streams and ultimately to the oceans. These losses can be accelerated by poor agricultural practices, and if streams, lakes, and inshore marine environments become enriched with P, eutrophication and algal blooms can occur. Phosphorus in agricultural products is transported to cities and is channeled into effluent. Some of this is recycled in the terrestrial environment and a small component is reused for agriculture, but a substantial proportion is transferred to oceans where it reenters the slowest part of the global P cycle (Cordell *et al.*, 2011). The P entering the oceans accumulates as insoluble sedimentary deposits which are normally only able to reenter the terrestrial P cycle after major geological events that bring submerged rock strata to the surface (timeframe is millions of years).

Unlike soil N, where significant inputs of nutrient occur from atmospheric sources (i.e., biological N_2 fixation and to a small extent by atmospheric deposition), soil P is only replenished by weathering of parent rock materials and through fertilizer applications with relatively small inputs from the atmosphere (usually in the form of windblown dust) (Smil, 2000).

Phosphorus inputs

Although weathering of parent materials is the initial source of P in soil, analyses of soils from chronosequences show that there is a decline in total soil P as soils age after their initial genesis. Systems with young soils may initially have high P content and are N-limited, but they become severely P limited and N enriched (due to biological inputs) over time. Soil genesis is also associated with a shift in the relative

contribution of organic P to total P content, with organic P generally becoming a more predominant component with time (Walker and Syers, 1976; Crews *et al.*, 1995).

Phosphorus fertilizers are used routinely to overcome soil P deficiency and improve agricultural production. Currently, some 18 Tg of P as fertilizer are used annually throughout the world (Cordell and White, 2011), with considerable disparity in usage across continents and within different agricultural systems. P-based fertilizers of inorganic origin are essentially derived from deposits of rock phosphate with some ~15 Tg of P being mined as phosphate rock (~160 Tg of mineral in total) per annum (Van Kauwenbergh, 2010). Crushed phosphate rock may be applied directly to soil as a fertilizer but its effectiveness depends on the P content of the rock, its reactivity with soil and the farming system in which it is being used. More commonly, phosphate rocks are processed to produce soluble, high-analysis fertilizers. The manufacture of phosphate fertilizers dictates that P is usually applied in combination with other mineral nutrients, for example, Ca (when applied as triple superphosphate), Ca and S (as superphosphate), and N (as mono- (MAP) and diammonium phosphate (DAP)). This is used to advantage in agriculture, enabling appropriate mixtures of nutrients in fertilizers to address specific soil and crop requirements. Further treatments of mineral P fertilizers can be used to add other essential nutrients as required (e.g., micronutrients such Mo, Zn, etc.). Organic forms of P fertilizer and organic-based products are also widely used in different farming systems. Organic-based P fertilizers are derived predominantly from animal manures that are used either directly or after composting. This may account for a further 8–17 Tg P applied to agriculture per year (Cordell *et al.*, 2009; Bouwman *et al.*, 2011) Organic P from other recycled forms of animal and plant biomass is also used, along with P collected from industrial waste streams. The forms and amounts of P fertilizer that are used as inputs to farming systems across the world vary considerably and are governed by the specific nutrient requirements of each farming system, socioeconomic issues, access to product, and affordability.

Forms of phosphorus in soil and availability to plants

Phosphorus that is contained in parent rock is not available to plants. Plant-available P occurs as orthophosphate anions in soil solution, which are replenished by exchange with orthophosphate that is adsorbed to soil constituents such as clay minerals or by rapid mineralization of labile forms of organic P. Less available forms of P occur as components of sesquioxides (amorphous oxides of Fe and Al), as poorly soluble or precipitated forms of P (primarily associated with Ca in alkaline soils and with Fe and Al in acidic soils), and as a component of organic matter. Reactions of orthophosphate with soil minerals are complex, time dependent, and are influenced by factors such as the orthophosphate concentration of soil solution, moisture, mineralogy, soil pH, and microbial activity (McLaughlin *et al.*, 2011). Here, the reactions involving plant-available phosphate are distinguished (orthophosphate-adsorption and desorption reactions) from the continuing reactions of phosphate with soil that lead to phosphate accumulations in various forms that are only sparingly available to plants, by referring to the latter as P-sorption reactions. The balance between adsorption/desorption and the rates of P-sorption differ markedly between soils, depending on their chemistry, intrinsic P content, and their history of fertilizer P additions (Barrow *et al.*, 1998). These reactions influence the availability of P to plants, the need or otherwise for P fertilizer, and the efficiency with which P fertilizers are used.

Organic forms of P typically account for between 30% and 80% of the total soil P with higher predominance in grassland soils and native systems as compared with cropping soils. A large proportion (approximately 50%) of the organic P remains poorly identified and exists as high molecular weight material that is associated with the humic fraction of soil organic matter. Identified forms of organic P in soil include monoesters and diesters, with lesser amounts of teichoic acids and phosphonates (Condron *et al.*, 1990). Monoester P occurs predominantly as cation derivatives of inositol hexakisphosphates (mainly as phytate) and its lower order derivatives (typically up to 30%; Turner *et al.*, 2002), whereas sugar phosphates and diester P (e.g., nucleic acids and phospholipids) constitute a smaller (approximately 5%) component. Organic P compounds in soil similarly undergo adsorption (desorption) and precipitation reactions and are associated with soil minerals or as part of the soil organic matter (Anderson, 1980).

Utilization of soil P by plants

Only a small proportion (generally less than 1%) of the large amount of P in a soil is immediately available to plants. Roots take up P as orthophosphate anions from the soil solution that is held as a film around soil particles. However, the concentration of orthophosphate in solution is often very low (typically less than 5 μM; Conyers and Moody, 2009). Phosphate uptake by plant roots readily creates a concentration gradient between the 'bulk' soil and the root surface. Unlike NO_3^-, which is very soluble and can be moved to plant roots by mass flow of soil water, orthophosphate anions are relatively immobile in soil and movement toward the root occurs by diffusion (Barber, 1984). In any particular soil, the rate of P diffusion to the root is determined by the size of the concentration gradient and the ability of the soil to replenish orthophosphate removed from the soil solution. If the rate of supply of orthophosphate to a plant is less than the rate of uptake needed for maximum growth, the soil is defined as P-deficient for plant growth. Under these circumstances in agriculture, the concentration of orthophosphate in soil solution and its concentration-dependent rate of diffusion may be increased by application of fertilizer.

Plants are well adapted to obtain P from soil and use a wide range of mechanisms to increase access to soil P or increase the availability of orthophosphate (Richardson *et al.*, 2009). Characteristics of roots that assist exploration of soil and acquisition of P include: high root mass and rate of root elongation, high specific root length (length per unit root mass), long and dense root hairs that significantly increase root–soil contact, and, in some cases, the development of specialized root structures (e.g., proteoid roots in white lupins). Mobilization of P from soil pools can also be increased by root exudates. For example, acidification of the rhizosphere and release of organic anions may enhance phosphate desorption and increase the solubilization of

precipitated P, and release of phosphatase enzymes potentially increase the hydrolysis (mineralization) of organic P.

Role of microorganisms in soil and biological transformations of P

Microorganisms play a critical role in the transformation of soil P between inorganic and organic P pools and in mediating the availability of P to plants (**Figure 2**). Microorganisms increase P availability though mechanisms that include solubilization and mineralization of orthophosphate from soil inorganic and organic P, direct enhancement of uptake through extending the root system (e.g., mycorrhizal associations; Smith and Read, 2008), and by stimulation of root growth through phytohormones (Richardson *et al.*, 2009). The microbial biomass also contains a substantial pool of immobilized P, which accounts for approximately 2–5% of total soil P (Oberson and Joner, 2005). Although microorganisms readily immobilize P from applied fertilizer and organic residues (McLaughlin *et al.*, 1988), they also release significant quantities of P back to soil solution through turnover as either orthophosphate (and polyphosphates) or organic forms that are readily mineralized (e.g., nucleic acids) and thus potentially available to plants (Seeling and Zasoski, 1993). Turnover of P within the microbial biomass is rapid and can be independent of any net change in the size of the microbial pool (Oberson and Joner, 2005). Higher rates of turnover have been observed in unfertilized soils and in soils amended with organic inputs. The capacity for microorganisms to mobilize P from sparingly available pools of soil P and provide orthophosphate to plants is increased considerably within the rhizosphere where there is a large supply of root-released C (Richardson and Simpson, 2011). However, the relative importance of microbial processes to P mobilization as compared with direct plant mechanisms remains poorly understood.

The role of mycorrhizal fungi and their contribution to the uptake of soil P by agricultural plants is likewise not clear. It is well established that agricultural plants show varying dependency on mycorrhizal infection (i.e., arbuscular mycorrhizas; AM) and the extent of host infection is influenced strongly by plant species, plant P status, and the availability of soil P. In conventional agricultural systems, which operate at high levels of plant-available soil P, the reliance of plants on mycorrhizas for P uptake is, therefore, often reduced. In contrast, in many organically managed (Mäder *et al.*, 2000) and biodynamic farming systems (Ryan *et al.*, 2000), mycorrhizal fungi (both AM and ectomycorrhizas) are considered to play a greater role in the P nutrition of plants, primarily as a function of lower soil P status.

Management of soil P fertility

Despite the large amounts of total P found in soil, plant growth is restricted by P deficiency in many soils throughout the world, with plant growth affected on more than 30% of the world's arable land (Vance *et al.*, 2003). Some agriculture is practiced in P-deficient landscapes. This includes situations where: (a) constraints on achievable yields imposed by other more limiting resources (e.g., extensive, water-limited grazing systems in northern Australia; McIvor *et al.*, 2011) are more substantial than P limitations and make use of P fertilizers uneconomic, (b) socioeconomic circumstances do not allow applications of P fertilizer (e.g., low-input agriculture in some developing economies of Africa; Sánchez, 2010), or (c) 'rule-based' agricultural production philosophies which restrict sources of P that may be used as an input (e.g., 'biodynamic' farm enterprises; Burkitt *et al.*, 2007). These systems typically have low productive capacity and may only require small inputs of P to balance P removal in products (e.g., McIvor *et al.*, 2011). However, 'plant-available' P declines when P inputs are low or absent and net extraction of soil P can occur as a result of P export in products and other losses (e.g., soil erosion; **Table 4**). Depletion of P from low-P soils is not sustainable in the longer term and can ultimately lead to nutrient exhaustion and declining production over time. Examples of this have been observed during colonial agriculture in Australia (Kirkegaard and Hunt, 2010), modern low-input farming (e.g., Burkitt *et al.*, 2007), and in subsistence agriculture in Africa (Sánchez, 2010). For production in a farming system to be sustainable, a minimum requirement is that exported P should be replaced by P inputs.

More commonly, P fertilizers are applied to agricultural crops either when an increase in the level of 'plant-available' P in the soil will deliver higher crop yields or to maintain soil fertility when levels are already adequate for high productivity. Crops are typically fertilized to achieve 'critical' soil P fertility levels, usually defined as the plant-available orthophosphate concentration of the soil that will support near-maximum crop yield (Peverill *et al.*, 1999). Various extractable-P soil tests are used to estimate plant-available P. The 'critical' soil test level for a crop–soil system reflects both the P requirement of the crop species and the P supply characteristics of the soil in which it is growing.

The amount of P that must be applied each year to achieve and then maintain soil fertility includes a component of P to build soil fertility if it is below the required level of plant-available P and another to hold soil fertility at the target level. Because soils vary considerably in their rates of P-sorption and desorption, and in their potential for P losses (erosion, runoff, and/or leaching), the amount of P applied to maintain soil P fertility can sometimes greatly exceed the export of P in products (**Table 4**).

Phosphorus-use efficiency and the P balance of farming systems

Phosphorus inputs are required for agriculture to be both sustainable and productive. In contrast to N, where N_2-fixing legumes provide an alternative to fertilizers, maintenance of soil P fertility is dependent on P inputs from external sources along with efficient recycling of P within the soil–plant–animal system (**Figure 2**). Global P 'reserves' (high-quality phosphate rock deposits) and P 'resources' (phosphate rock deposits of lower quality or harder to access; not currently economic to mine) are extensive (Van Kauwenbergh, 2010). However, the high-quality phosphate rock reserves are effectively a finite resource because lower grade resources will be more costly to extract. Although it has been estimated that the world's known P reserves could supply P for 300–400 years at current rates of use (Van Kauwenbergh, 2010), issues concerning P scarcity, inequitable distribution of available P resources, and the reliability of global supply have been raised in relation to long-term global food security (Cordell and White, 2011). Consequently, there are many reasons why it is

Table 4 Factors that determine the amount of fertilizer P to be applied to a crop or pasture

Factor	*Determinants*
Amount of P required to lift the plant-available P concentration of the soil to the target for soil fertility management	If a soil is below the target soil fertility required to achieve the production goal for the crop, extra P must be applied to increase the plant-available P concentration of the soil to the target level. The amount of P varies depending on the P-sorption capacity of the soil (Burkitt *et al.*, 2001) and will be lower for soils with low P-sorption capacity (e.g., sandy soils or soils where P-sorption sites are nearly saturated as a result of naturally high P fertility or previous fertilizer applications). The soil test target for soil P management may or may not be the 'critical' P level determined for the crop–soil system, but it should not exceed this level as no further increase in production would be achieved.
Amount of P exported in the agricultural product	Examples: *Animal liveweight* – P concentration is approximately 7–8 g kg^{-1} liveweight for a mature cow or sheep (SCA, 1990); thus, if a 50 kg mature sheep is removed from a field that is being grazed continuously and is replaced by a 25 kg weaner sheep, approximately 0.2 kg of P would be exported from the field. *Milk* – Average P concentration of cows' milk varies between approximately 0.9 and 1.4 g kg^{-1}, depending on breed (SCA, 1990); a Friesian cow producing 20 kg milk per day with a P concentration of 0.9 g P kg^{-1} would result in 18 g of P being exported from a dairy farm per cow each day. *Cereal grain* – if P concentration of the grain is 3.5 g kg^{-1} DM, ~3.5 kg of P will be exported per tonne of grain yield.
The amount of P that accumulates annually in the agricultural field	(a) P may be immobilized in soil organic matter fractions that resist degradation (Dalal 1977; Anderson, 1980) (b) Phosphate may accumulate in sparingly available soil pools due to sorption or precipitation reactions of inorganic P (Barrow, 1983; McLaughlin *et al.*, 2011). Soils with high P-sorption capacity will accumulate more phosphate in this way. (c) P may become ineffective for plant growth in grazed fields through uneven dispersal of animal excreta (Williams and Haynes, 1992). Although uneven distribution represents no 'net' change in the amount of P returned to a grazed field, it results in localized area with excessively high P concentrations and increases the amount that must be applied to achieve target soil fertility levels in the rest of the field (Simpson *et al.*, 2011).
Losses due to soil erosion, leaching, and/or in runoff	P losses due to erosion and surface runoff occur because of the close association of P with soil particles (i.e., P adsorbed to clay surfaces, P associated with soil minerals, or P contained within organic matter, including animal manures) but can be minimized by soil conservation and fertilizer management practices (Hart and Cornish, 2012). Loss of P due to leaching varies considerably with soil type. On soils with moderate to high P-sorption capacity is generally considered to be relatively small (i.e., less than 5% of applied P; Melland *et al.*, 2008). However, on low P-sorbing soils losses of phosphate due to leaching can be significant and require specific management interventions; for example, through the use of less-soluble forms of fertilizer. Organic forms of P in soil leachate and in runoff may also be a significant source of P loss due to greater mobility of organic P in soil solution compared with phosphate anions (Toor *et al.*, 2003).

important to achieve high efficiency in the use of P resources. There will also be an increasing need to close the more rapid terrestrial component of the P cycle by recovering more P from waste streams for use as fertilizer. At present, the extent of P recovery is determined by the need to reduce waste streams and pollution associated with them and is constrained by the high cost of P recovery compared with fertilizer manufactured from phosphate rock. In developing economies, improved P use efficiency can mean development of farming systems that are more productive at low P availability because fertilizer is already a relatively expensive input. Ultimately, these systems are more likely to migrate to increasing use of P fertilizers to ensure improved food security (Sánchez, 2010). By contrast, in more intensive agriculture, there is often a need to minimize inefficient use of P inputs and to reduce potential loss of P to the environment (Sharpley *et al.*, 2001; Schröder *et al.*, 2011).

The most efficient use of P fertilizer occurs when P fertilizer inputs are approximately equal to the quantity of P exported in agricultural products (i.e., P balance efficiency ($100*P_{output}/P_{input}$) = 100%: Helyar, 1998). This can sometimes be achieved in low-input farming systems (e.g., McIvor *et al.*, 2011), but these systems will have characteristically low production. When P is the major limitation to potential production, low P inputs may also result in low land, water, and other resource-use efficiencies. In more intensive agriculture, P-balance efficiency is determined largely by the P-sorption capacity of the soil. Agriculture practiced on low P-sorbing soils (where P-buffering capacity is low because sorption sites for P are close to saturation and soil P fertility is relatively high) can

achieve relatively high P-balance efficiencies. For example, greater than 90% P-balance efficiency has been reported for cereal production using appropriate rates of P input to maintain fertility on soil with a long fertilizer history (Johnston and Syers, 2009). However, in P-deficient soils with moderate to high P-sorption capacity, P-balance efficiencies are commonly approximately 10–30% and 45–60% for grazing and cropping systems, respectively (Simpson *et al.*, 2011; Weaver and Wong, 2011). In these cases, P inefficiency is mainly associated with unavoidable accumulation of P in the soil (McLaughlin *et al.*, 2011; Simpson *et al.*, 2011). Analysis of western European farming systems by Sattari *et al.* (2012) similarly indicates that in the period from 1965 to 2007, inputs of P fertilizer to crops exceeded on average that removed in product by approximately three-fold. The application rates of P in Europe have declined since the 1980s; however, there has been no accompanying reduction in plant P uptake, indicating that soils (on average) have been fertilized to levels in excess of crop requirements and that plant assimilation of P is being sustained by utilization of soil reserves. However, where the P-sorption capacity of the soil is low, such imbalances in P use are also more likely to be indicative of P losses to the wider environment where they can cause substantial environmental problems (Schröder *et al.*, 2011). This scenario is mirrored in other parts of the world where there is high use of P fertilizers (e.g., USA, Sharpley *et al.*, 2001; China, Li *et al.*, 2011).

Conclusion

The productive capacity of agricultural land is largely dependent on the access by plant roots to available forms of key essential nutrients in soil. The current global demand for food now exceeds the ability of natural soil processes to supply sufficient N and P without human intervention supplying additional external inputs to accelerate the flux of N and P through their respective nutrient cycles (Smil, 2001). There are strong economic and environmental incentives to improve the efficiency of both N and P use in farming systems.

Different approaches to improve the efficiency of use of soil and fertilizer N and to minimize N losses from the plant–soil system aim to either:

1. Increase plant N demand through choice of plant species and/or genetic selection to enhance the efficiency of acquisition or recovery of N from soil, or improve the internal efficiency with which N is used to produce biomass. Plant N demand can also be increased through management by applying good agronomic practices to address factors that would otherwise restrict plant growth such as disease, weeds, pests, and soil constraints to root growth (Crews and Peoples, 2005),
2. Manipulate N supply to better match plant N demand through presowing soil testing of soil mineral N status, N-budgets and decision-support tools, the timing, placement, rate, and form of N input applied, or the use of technologies to slow the release of plant-available forms of N (Crews and Peoples, 2005), or
3. Capture excess inorganic N before it can be lost by planting cover ('catch') crops during periods of fallow between crops, or interplanting annual crops with perennials (perennial polyculture).

The options for achieving more efficient use of P are similar irrespective of whether the aim is to develop crops that yield more in low-P soils, crops that will yield well when supplied only the P that will be exported in products, or farming systems that are less prone to P losses to the wider environment. These include:

1. Targeting fertilizer use to ensure that crops are only fertilized to their 'critical' P requirement, and better use must be made of the P that has been accumulated in agricultural soils throughout the world (Sattari *et al.*, 2012; Stutter *et al.*, 2012),
2. Application of fertilizer technologies to minimize P losses from low P-sorbing soils or fertilizers that avoid reactions in soils that lead to accumulations of sparingly available P (McLaughlin *et al.*, 2011).
3. The use of crops with lower critical P requirements and improved yield in low P soils as this will lead to more efficient use of the P that is applied as fertilizer and will lessen the opportunities for nutrient leakage (Simpson *et al.*, 2011).
4. Development of plant genotypes, agronomic management, and microbial options that improve access by crops to sparingly available and accumulating pools of P in soil (Richardson *et al.*, 2011).

Glossary

Convergent breeding A breeding method involving the reciprocal addition to each of two inbred lines of the dominant favorable genes lacking in one line and present in the other.

Dioecious Having the male and female reproductive structures on separate plants.

Geitonogamy Pollination, by pollen falling from upper flowers to the lower flowers by gravitational pull.

Orthotropic The vegetative propagule assumes an upright or normal tree form.

Patch budding Plant budding in which a small rectangle of bark bearing a scion bud is fitted into a corresponding opening in the stock.

Plagiotropic Branches that arise from the axils of leaves of the orthotropic shoots.

Polygamodioecious Plants bearing bisexual as well as either male or female flowers.

Protogyny The female phase preceding the male phase a few days to weeks.

Schizocarp A dry fruit that, when mature, splits up into mericarps.

Introduction

Spices are a part of history, associated with wars and romance. 'King of Spices' (black pepper) and 'Queen of Spices' (small cardamom) reign supreme in the global flavors and food industry. In search of spices, Columbus discovered the New World, whereas Vasco da Gama, a Portuguese navigator, with the same pursuit landed at Calicut on the Malabar Coast of India on 20 May 1498. This changed the history of India and the world at large. Spices were known as early as 2100–2600 BC and were well known in Greek civilization. Spice crops are mainly confined to Southeast Asia, some parts of Africa, and South America. The crops are highly location specific and are grown in certain agroclimatic conditions that vary according to the crop.

There are no precise data on the area and production of spices at the global level. It has been estimated that globally these crops are grown on an area of 8 million ha contributing to 31.6 million tons of spices annually. India's share to world spices production is 6 million tones amounting to 19% (DASD, 2014). The global spice industry amounts to 1.1 million metric tons, accounting for US$ 3.475 billion in value. India's share at the global level is 0.575 million metric tons, accounting for US$ 2.037 billion i.e., 52% in volume and 58.6% in value (see Spices Board of India website).

During the period from 1994 to 2004, the value of spice imports increased on an average by 6.8% per year, whereas the volume increased by 5.9% during that time. In 2004, world import in spices consisted of 1.547 million tons valued at US$ 2.97 billion (ITC, 1999). In the period 2000–02, world import volumes of spices grew at an annual average rate of 7%, whereas import values decreased, on average, by 5% annually. This negative growth in value is attributed to dramatic decreases in the value for whole pepper during 2000/01 – by approximately 40% and a further 18% in 2002/03. Although import volumes stabilized from 2003 to 2004, that of values grew by 4.6%. This upward value trend is mainly attributed to higher market prices for major commodities, such as capsicum, vanilla, ginger, bay leaves, and spice mixtures. There was a growing trend toward the trade of processed spices, which bring higher prices. The growing demand for value-added processing of spices, such as capsicum and ginger, offers business opportunities for the food and extraction industries in international markets. The major markets in the global spice trade are the US, the European Union, Japan, Singapore, Saudi Arabia, and Malaysia. The principal supplying countries are China, India, Madagascar, Indonesia, Vietnam, Brazil, Spain, Guatemala, and Sri Lanka.

Spices are aromatic plants that are used mainly for imparting flavor, aroma, and pungency and for seasoning food. Many of them are also used in medicines and perfumery. The International Standards Organization lists approximately 109 plant species as spices. India is considered the magical land of spices. From the Indian subcontinent, many major spices spread over to most of the tropical part of the world. Peninsular India is a rich repository of spices, and more than 100 species of spices and herbs are grown on approximately 3.47 million ha with an annual production of 6.33 million tons and accounts for approximately 52% of the global trade. Black pepper, cardamom, ginger, turmeric, capsicum, cinnamon, clove, nutmeg, tamarind, and vanilla constitute the major spices. Seed spices like coriander, cumin, fennel, fenugreek, dill, caraway, anise and herbal spices like saffron, lavender, thyme, oregano, celery, anise, sage, and basil are also important. The spices are cultivated in many countries in a wide variety of geographical regions. Each country has its own traditional cultivars/races/types of these spices.

Black Pepper (*Piper nigrum* L.)

Black pepper is considered the King of Spices and is the most widely used spice in the world. Mature berries (fruit), harvested and dried, are the black pepper of commerce. Ripe berries are harvested and decorticated for production of white pepper. It is valued for its characteristic pungency and flavor, the former due mainly to the alkaloid piperine and the later due to a volatile oil. Black pepper has multiple uses in the

processed food industry, the kitchen, in perfumery, traditional medicines and in beauty care.

Black pepper is mainly grown in tropical regions of the world, such as India, Indonesia, Malaysia, Sri Lanka, Thailand, China, Vietnam, Cambodia, Brazil, Mexico, and Guatemala. The estimated production of black pepper (including long pepper) in the world is approximately 409 899 ton on an approximate area of 583 897 ha. The International Pepper Community members namely India, Brazil, Malaysia, Indonesia, Vietnam, and Sri Lanka are the main suppliers to the world market. Major importers of Indian pepper include USA, Russia, Canada, Germany, Italy, Netherlands, France, Japan, Morocco, Poland, UK, Canada, and Saudi Arabia. Black pepper accounts for approximately 6.2%.of the total spices traded internationally. Demand for black pepper and its products in the world market are increasing at the rate of 3.2% annually in volume and 8% in value.

The genus *Piper* comprises around 1200 species, approximately 60% of which occur in Central and Northern South America. The Malabar Coast of South West India is the traditional home of black pepper, grown from almost sea level to approximately 1500 m. Black pepper was the first oriental spice to be introduced into the western world.

Black pepper is a perennial woody climber. Under cultivation, pepper vines are trailed on either living or other nonliving supports, as columns 5–10 m tall (**Figure 1**). The climbing woody stems have swollen nodes with roots at each node anchoring the vine to the support. Pepper plants exhibit two types of branches: the main stem and orthotropic vegetative climbing shoots that adhere to the support with short adventitious roots at nodes; and flowering or plagiotropic (sympodial habit of growth) branches that arise from the axils of leaves of the orthotropic shoots. The pepper plant has mostly surface-feeding root system. The flowers are minute, white to light green, arranged spirally on fleshy peduncles. The cultivated pepper is self-pollinated, and pollination is by pollen falling from upper flowers to the lower flowers by gravitational pull, a process called 'geitonogamy.' The fruit (berry) is a single-seeded drupe with a fleshy pericarp and hard endocarp, pungent and red when ripe, black when dried. White pepper is the dried berries after removing the pericarp (**Figure 1**).

Wild populations of *P. nigrum* are found extensively distributed in many forest areas. Wild forms are usually dioecious but most cultivated ones are bisexual. It is thought that the bisexual forms might have evolved due to unconscious selection for high-yielding types during domestication. Many cultivated types exhibit protogyny with the female phase preceding the male phase a few days to weeks.

Black pepper is cultivated either as a pure crop on wooden poles in Indonesia, Malaysia, Vietnam, Brazil, and on live supports like *Erythrina indica*, *Glyricidia*, Jack trees, Silver oak, etc. in India and Sri Lanka or as a mixed crop along with a wide variety of plantation crops, such as coffee, tea, coconut, and arecanut (**Figure 1**).

More than 100 cultivars of black pepper are known but only some of them are popular. Cultivar diversity is richest in the Indian state of Kerala. The cultivar Karimunda is popular and gives consistent yields under varying agroclimatic conditions. Kottanadan, Kumbhakodi, and Aimpirian are cultivars with high contents of oleoresin and essential oils and hence give high-quality pepper. Others such as Neelamundi, Balankotta, Chumalakodi, Narayakodi, Kalluvally, Kuthiravally, Malligesara, and Thommankodi are popular in certain locations. The hybrid Panniyur-1 is the most preferred variety and is spreading throughout the world. Cultivars Kuching, Lampung Daun Kocil, Belantung are popular varieties in Malaysia and Indonesia and Vinh Linh is another popular variety from Vietnam (**Figure 1**). Mutation breeding and polyploidy breeding methods were attempted in Sri Lanka and India. No resistance was observed in cultivated black pepper for all the three major diseases or pests viz. Phytophthora foot rot (*Phytophthora capsici*), burrowing nematode (*Radopholus similis*), and pollu beetle (*Longitarsus nigripennis*; Sarma, 2010). *Piper colubrinum*, a distant relative from Brazil, was found to be resistant to all three of these pathogens and pests. Efforts are underway to bring these characters into cultivated black pepper using interspecific hybridization and also through biotechnological approaches (Ravindran and Kallupurackal, 2000).

The best collection of black pepper genetic resources is conserved at the Indian Institute of Spices Resources, Kozhikode, India with more than 2900 varieties in the collection. They are conserved in clonal field repositories. Considerable variability exists among cultivars with respect to morphology, yield, and quality, but variability for resistance to biotic and abiotic stresses is limited. Much of the germplasm has been evaluated for genetic variability with respect to yield, quality, and reaction to biotic and abiotic stresses, and promising clones have been identified.

Seedling progenies are never used for propagation as they segregate. Instead, runner shoots or top orthotropic shoots are typically used as vegetative planting materials. These shoots are cut into two to three node bits and planted in polybags housed in humid thatched nursery sheds. This method results in a success rate of 70–80% rooting. Alternatively, these shoots are allowed to grow either on polybags filled with potting mixture or on bamboo splits with coconut pith for multiplication (**Figure 2**).

Pepper, being a climber, requires a support (standard) for its growth and yield. In India, it is mostly cultivated in homestead gardens as a mixed crop on existing support trees. In Brazil, Indonesia, Vietnam, Malaysia (Sarawak), and Thailand pepper vines are usually supported on dead standards. Usually, the trees selected for support are raised for trailing pepper vines. A live support should be fast-growing with few branches, should tolerate periodical pruning, should not compete with other crops for resources and should not produce allelopathic chemicals.

Pepper can be grown as a companion crop, such as coconut, arecanut, or mango/jack. Pepper is also grown with perennial crops, such as coffee, cardamom, tea, and clove, utilizing the shade trees. The coffee/pepper cropping system is very profitable. In coffee plantations the silver oak tree (used as shade tree) is ideal for growing pepper with less competition for light and nutrients (**Figure 1**).

Bush Pepper

Pepper can also be raised in bush form. The fruiting lateral branches of any cultivar can be rooted and the resultant plant grown like a small bush, which flowers in the same year

Figure 1 (a) Black pepper – pure crop on wooden supports; (b) coffee – pepper cropping system; (c) tea-pepper cropping system; (d) variation in spike characters; (e) high-yielding variety 'Subhakara', a Karimunda cultivar from India; (f) high-yielding hybrid 'Panniyur-1' from India; (g) variety 'Vinh Linh' from Vietnam; (h) *Phytophthora*-tolerant variety 'Shakti'; (i) dried black pepper; and (j) dried white (top), ripened (left), and fresh green (right) pepper.

Figure 2 Left to right: Healthy black pepper nursery with rooted cuttings, multiplication using serpentine method and multiplication using the bamboo method.

Figure 3 Bush pepper in a pot and in the field.

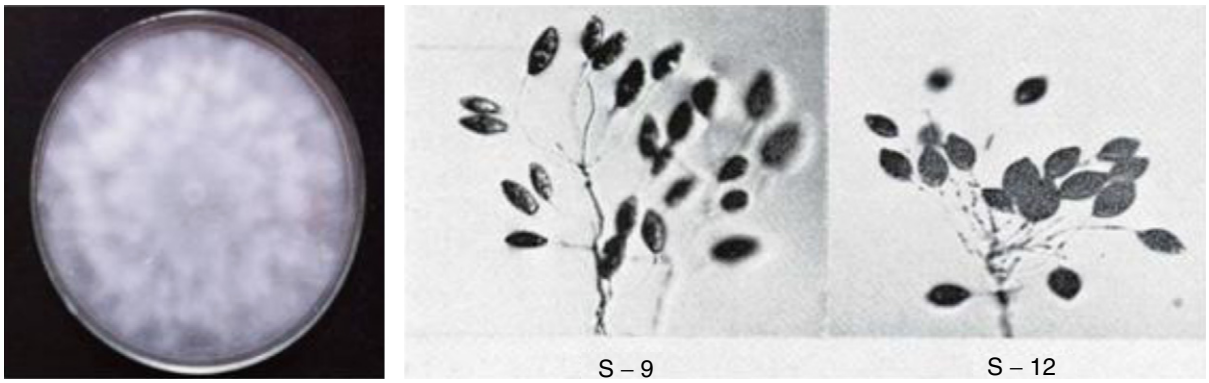

Figure 4 *Phythophthora capsici* in culture (left), as umbellate sporangiophore (center), and sympodial sporangiophore with zoosponagia (right).

and continues to yield throughout the year under irrigation (Figure 3).

These bush peppers can be accommodated well in homes and terrace gardens. The crop tolerates temperatures between 10 and 40 °C although above 32–34 °C is not conducive for productivity.

Pepper plants take 6–8 months from flower to harvest depending on the cultivar and rains. Whole spikes are hand-picked when a few berries in the spikes turn orange red. Harvesting is also done based on processing requirements. Harvested spikes are kept overnight for easy despiking. Berries are separated from spikes manually or mechanically using threshers. To give a uniformly lustrous black color and to prevent moldiness, the separated berries are dipped in boiling water for 1 min before drying. Drying is done both by sunlight for 7–10 days or using mechanical dryers to a moisture content of 10–12%. Dried pepper is cleaned to remove extraneous matter and graded according to size before packing.

Approximately 20 diseases have been described worldwide for black pepper. However, Phytophthora foot rot caused by *P. capsici* (Figures 4 and 5), slow decline caused by the nematode *R. similis*, (Figure 6), anthracnose and stunted disease complex caused by a virus (Figure 7) are the most serious ones (Holliday and Mowat, 1963; Sarma and Nambiar, 1982; Anandaraj, 1997; Sarma *et al.*, 2013). The spectrum of diseases in all the pepper-growing countries is

Figure 5 Phytophthora foot and root rot showing root symptoms (left), foliar wilting (center), and foliar lesions (right).

Figure 6 Black pepper showing (left) root symptoms of the knot nematode, *M. incognita*; (center) symptoms of root necrosis/rot by the nematode, *R. similis*; and (right) vines showing symptoms of slow decline caused by *R. similis*.

Figure 7 Black pepper showing symptoms (a) anthracnose leaf infection; (b) spike infection; (c) cucumber mosaic virus foliar infection; and (d) pepper yellow mottle mosaic virus infection.

very similar, particularly in the cases of stunted disease complex and Phytophthora foot rot. This would indicate a common origin of these diseases, probably India from where this crop has gone to other countries through planting material. Quarantine regulations have never existed between these countries. Nematodes, pollu beetle, mealy bugs, shoot borer, scale insects, leaf gall thrips, burrowing and root knot nematodes (*Meloidogyne incognita* and *R. similis*), and root

Figure 8 Biological control of Phytophthora foot and root rot of black pepper with *Trichoderma harzianum* formulation Left, nontreated plot; right, treated plot, showing dark green foliage.

mealy bugs (*Planococcus* spp.) are the major pests limiting productivity of pepper.

Solarized or nonsolarized soil mixes fortified with effective biocontrol agents, such as *Glomus fasciculatum* (vesicular arbuscular mycorrhiza fungus), *Trichoderma harzianum* or *Trichoderma viride* (**Figure 8**), and *Pseudomonas fluorescens*, *Pochonia chlamydosporia*, or *Paecilomyces lilacinus* and filled into polybags meant for raising rooted cuttings (Sarma, 2006; Sarma *et al.*, 2014). This method reduces root infection and ensures robust root-rot free planting material. Production of disease-free planting materials is imperative in establishing a healthy plantation.

Research work on isolation, cloning, and validation of full-length genes of pepper is in progress. Resistance gene candidates encoding the defense-related proteins, such as osmotin and β-1,3-glucanase, were cloned and sequenced from black pepper and *P. colubrinum*. Transcriptome sequencing of *P. colubrinum* and *P. nigrum* leaf samples challenge inoculated with *P. capsici* revealed the expression of many genes similar to those involved in secondary metabolism, metabolic processes, response to stress, flower development, and fruit ripening. Sequences similar to regulatory genes were also found (Nirmal Babu *et al.*, 2011).

Small Cardamom (*Elettaria cardamomum* Maton)

Small cardamom, the 'Queen of Spices,' is commonly cultivated beneath the evergreen forest trees of Western Ghats of South India, Sri Lanka, and Guatemala. Guatemala, where cardamom is grown largely on plantation scale, is the world's premier producer and exporter followed by India. The major consumers of cardamom are India, Saudi Arabia, other Arab countries, Europe, and Japan.

The most significant component of cardamom, as a spice, is the volatile oil with its characteristic aroma, described generally as camphory, sweet, and aromatic spicy. This is due to the presence of 1,8 cineole, di-terphenol, terpinyl acetate, limonene, sabinene, and borneol, which makes cardamom oil unique (Lewis *et al.*, 1966).

The evergreen forests of Western Ghats in India where natural populations of cardamom still exist is considered the native home of small cardamom. The genus *Elettaria* consists of seven species distributed in India, Sri Lanka, Malaysia, and Indonesia; of these, only *E. cardamomum* is economically important (Holttum, 1950). In India, the genus *Elettaria* is represented only by one species, *E. cardamomum*.

Cardamom is a herbaceous perennial (2–5 m in height) having underground (subterranean) rhizomes with aerial leafy stems (tillers) made of leaf sheaths (**Figure 9**). The suckers grow for approximately 10–18 months before flowering (Madhusoodanan *et al.*, 2002). The growth habit of the panicles and the shape as well as the size of the capsules varies in different cultivars/types of cardamom. Flowers are arranged in clusters known as *cincinni*, are bisexual, and occur from May to October. Bisexual flowers are self-compatible but cross-pollination is the rule. Honey bees contribute for more than 90% of pollination. Cardamom is a shade-loving plant that thrives well at elevations of 600–1200 m above sea level under an average annual rainfall of 1500–4000 mm and temperature range of 10–35 °C.

Cardamom germplasm is maintained as clonal field repositories in India with more than 1500 accessions. The main focus of cardamom breeding, in addition to high yield, bold capsules, and quality attributes, are resistance to viral and fungal diseases, and drought. The main breeding strategies are selection and hybridization. Convergent breeding programs designed to bring multiple resistance are in progress (Madhusoodanan *et al.*, 2002).

Cardamom is propagated both through seedlings and vegetatively through suckers. Clonal multiplication of cardamom ensures genetically uniform true-to-type planting material. Seedlings are raised in a nursery under partial shade using seeds from ripe capsules collected from high-yielding and healthy clumps. Cardamom seed has a hard seed coat, and scarification of seed with 25% nitric acid for 10 min followed by thorough washing in water before sowing assures above 80% germination. Soil solarization of seedbeds in cardamom nurseries enhances germination by 25%, reduces weed growth by 82%, and suppresses pest and disease incidence.

Small cardamom (**Figure 9**) requires a warm and humid climate fairly well distributed annual rainfall of 1500–5000 mm. Cardamom is a surface feeder; 70% roots are at a depth of 15 cm and hence availability of moisture at the root zone is important for good growth and yield. It is also susceptible to wind damage. Cardamom thrives well in moderate shade (50–60% light).

The crop starts flowering during early monsoon showers in India and comes to bearing during July–August, with harvest

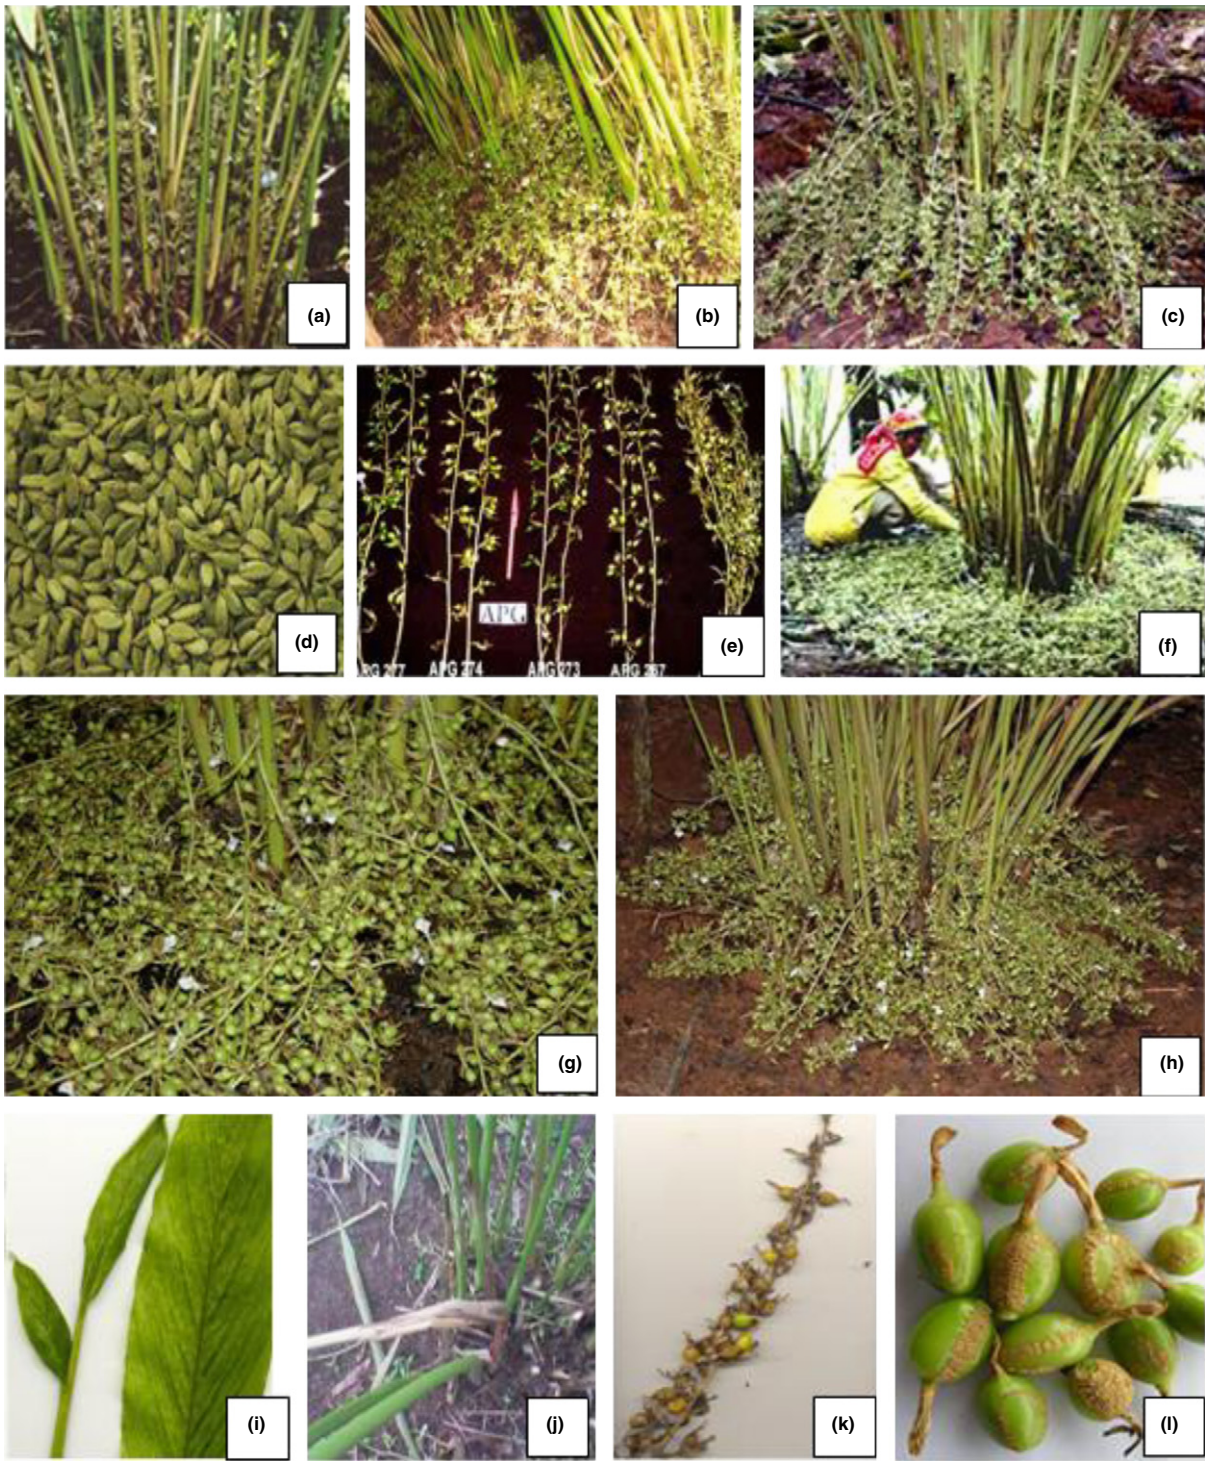

Figure 9 Small cardamom (a) Mysore type; (b) Malabar type; (c) Vazhuka type; (d) dried cardamom; (e) variation in panicle branching patterns; (f) high-yielding variety 'Mudigere1'; (g) high-yielding high-quality variety 'Kodagu Suvasini' suitable for high-density planting; (h) high-yielding katte-resistant variety 'Vijetha'; (i) symptoms of katte virus; (j) rhizome rot; (k) capsule rot; and (l) thrips infestation.

generally completed by October–November. This highly humid warm climate so congenial to growth and productivity is also congenial for fungal diseases; among them are capsule rot caused by *Phytophthora meadii*/*P. nicotiana* and clump rot caused by a *Pythium–Fusarium* complex. The root knot nematode *M. incognita* is another serious soil-borne pest. Three viral diseases are important, namely, katte or mosaic disease (Figure 9), kokke kandu, and banana bract mosaic virus. A minor viral disease, nilgiri necrosis virus (Naidu and Thomas, 1994) has also been reported (Siljo *et al.*, 2013).

Katte virus is a Potyvirus transmitted by the banana aphid *Pentalonia nigronervosa*. The disease is not fatal but results in a gradual decline in the vigor and productivity of the affected clumps (Venugopal and Naidu, 1984; Naidu and Thomas, 1994). The disease starts as chlorotic spindle-shaped streaks that later merge to produce a mosaic pattern of the disease (Figure 17). Studies on the coat protein and 3′ untranslated sequence of a Karnataka (Sakleshpur) isolate indicated that the virus is a new member of the genus, *Macluravirus*, family Potyviridae (Jacob and Usha, 2001). At least six distinct strains of the virus have been reported (Jacob *et al.*, 2003). Both serological and reverse transcription polymerase chain reaction methods are available for the detection of the virus in plants.

Cardamom plants start bearing fruits (capsules) in the second year after planting and satisfactory yield is obtained starting in the third year. It takes 110 days from flowering to fruit maturity. Time and duration of harvest depend on the climate, varietal differences, and irrigation. Fruits are hand-picked just before fully ripe to get maximum green color during curing. Capsules are processed within a day after harvest. Processing consists of washing, curing (drying), cleaning, polishing, sorting, grading, and packing. Capsules immediately after harvest are washed in clean water to remove adhering soil. Sometimes capsules are treated with 2% washing soda (sodium carbonate) for 10 min to stabilize the chlorophyll and impart a grass better green color. After washing capsules are dried to a moisture content of 7–20%, in drying houses by heat radiation. Dried capsules are rubbed with coir mat/gunny cloth/steel mesh and sieved to remove the plant debris, and graded according to size and color.

Large Cardamom (*Amomum subulatum* Roxb.)

Large cardamom (Figure 10) is one of the main cash crops cultivated mainly in India, Nepal, and Bhutan. It is also grown to some extent in Thailand, Laos, Cambodia, and China. The major importing countries are China, Arab countries, Pakistan, Vietnam, Korea, and Japan. It is used as a spice in Ayurvedic preparations. It contains 2–3% essential oil and possesses medicinal properties as carminative for stomach ache, diuretic, cardiac stimulant, and antiemetic.

Large cardamom is a perennial herb having subterranean rhizomes that give rise to leafy shoots (pseudostem) and spikes. Mature plants range in height from 1.5 to 3.0 m. The inflorescence is a dense spike on a short peduncle bearing 40–50 flower buds in an acropetal sequence. The fruit is a trilocular many seeded capsule. The capsule wall is reddish brown to dark pink. Large cardamom is essentially a cross-pollinated crop. Flowering is completed in 75–125 days from April to June at lower altitudes and from May to July at higher altitudes, depending on the weather conditions and the cultivar. The flowers remain viable for approximately 14 h after opening. Bumble bees (*Bumbus* sp.) are the main pollinators due to their compatible size followed by honey bees (*Apis dorsata*).

India has the largest collection of large cardamom with more than 300 accessions. There are several cultivars, such as Ramsey, Golsey, Sawney, Ramla, Chivey Ramsey, Garday Seto Ramsey, Seto Golsey, Ramnag, Madhusay, Red Sawney, Green Sawney, Mingney, and Barlanga (Gyatso *et al.*, 1980; Subba, 1984). Ramsey, Sawney, Golsey, Ramla, and Varlanga are the most popular with Seremna gaining importance in lower altitudes. Bebo is another cultivar from Arunachal Pradesh. Barlanga, Ramsey, and Ramla are well suited to higher altitudes, Golsey for lower altitudes, and Sawney with bold capsules is widely adaptable to different elevations. Varlanga is a high-yielding cultivar suitable to low, medium, and high altitudes. Most cultivars are susceptible to the viral diseases 'chirkey' and 'foorkey', but Golsey is relatively tolerant to chirkey. Ramla with bold dark pinkish capsules is moderately tolerant to chirkey. Leaf blight and leaf streak are the other two important fungal diseases in Large cardamom (Figure 10).

Large cardamom is propagated using either seeds or suckers. Although seed propagation reduces spread of viruses, clonal propagation with adequate precaution ensures genetic purity and high productivity. Efficient micropropagation technology for virus-free clonal propagation of large cardamom is also available. The crop grows well under the shade of trees at altitudes ranging from 1000 to 2000 m above sea level. For successful cultivation of this crop, the mean minimum and maximum temperature requirements are 6 °C during winter months and 25 °C during warm months. Well-drained loamy soils are rich in organic matter and nitrogen, low in phosphorus and medium in potash with a pH range 4.5–6.0 are ideally suited for large cardamom cultivation.

It takes approximately 4 months for the fruits to mature. Harvesting is done once a year by collecting spikes containing ripe fruits with the help of a special chisel-shaped narrow knife made especially for this purpose. The individual capsules are separated by hand, cleaned, and dried before marketing. The quality of large cardamom depends mainly on external appearance, i.e., color, uniformity in size, shape, consistency, texture, and flavor. 1,8 Cineole contributes to pungency, whereas α-terpinyl acetate adds a pleasant aroma.

Ginger (*Zingiber officinale* Rosc.)

Ginger an underground rhizome (Figure 11) is used as spice and condiment. In Indian and Chinese systems of medicines, it is also used to treat liver complaints, flatulence, anemia, rheumatism, piles, and jaundice. The main areas of ginger cultivation are India, China, Nigeria, Indonesia, Jamaica, Taiwan, Sierra Leone, Fiji, Mauritius, Brazil, Costa Rica, Ghana, Japan, Malaysia, Bangladesh, Philippines, Sri Lanka, Solomon Islands, Thailand, Trinidad and Tobago, Uganda, Hawaii, Guatemala, and many Pacific Ocean islands. India is the largest producer of dry ginger in the world contributing approximately 30% of the world's production.

The genus *Zingiber* consisting of approximately 150 species is widely distributed in tropical and subtropical Asia. It is thought to have originated in Southeast Asia, but was under cultivation from ancient times in India. The other important taxa of this genus are turmeric, cardamom, large cardamom, and several other species having economic and medicinal importance. Ginger is not found in the truly wild state.

Ginger contains 2–3% protein, 0.9% fat, 1.2% minerals, 2.4% fiber, and 12.3% carbohydrate and is a good source of calcium, phosphorous, iron, and vitamins. The volatile oils (lisabolene, cinol, phellandrene, citrol, borneol, cibonellol,

Figure 10 Large cardamom (a) field view; (b) flowers; (c) fruits; (d) frost injury; (e) 'chirkey' (mosaic) disease; (f) 'foorkey' disease, showing extensive tillering and sprouting of stunted shoots; (g) leaf blight (*Colletotrichum*); and (h) leaf streak (*Pestalotia*) disease.

geranial, linaloal, limoline, zingiberol, zingiberene, and camphenes), oleoresin (gingenol and shogaol), phenols (gingeol and zingerone), proteolytic enzyme (zingibain), vitamin B_6, vitamin C, calcium, magnesium, phosphorus, potassium, and linoleic acid are important constituents of ginger. The pungency of ginger is due to gingerol, whereas the aroma is due to the volatile oils lisabolene, zingiberene, and zingiberol.

Ginger is a herbaceous perennial but is usually cultivated as an annual (Figure 11) for its underground branched rhizome. Adventitious roots and storage roots arise from the nodes of these rhizomes. The ancillary buds shoot up as leafy stems known as pseudostems, which die out annually, whereas the plant continues to live through its rhizome. Flowers are borne on a spike produced in a peduncle different from the aerial leafy stem and arising directly from the rhizome. Ginger is not known to set seeds (Purseglove *et al.*, 1981; Ravindran and Nirmal Babu, 2005; Ravindran *et al.*, 2005; Nirmal Babu *et al.*, 2012a).

Though there is no natural seed set in ginger, reasonable variability exists for yield and quality attributes. Cultivar diversity is richest in China followed by India where many distinctly different morphotypes have been identified. A good

germplasm collection of ginger with more than 1000 accessions is maintained in India. A few high-yielding exotic cultivars, such as 'Rio-de-Janeiro' with a bold rhizome, fair skin, pungent, flavored, and less fibrous; 'China' with bold rhizome, yellowish-white skin, highly pungent, flavored and fibrous; 'Jamaica' with bold rhizomes, white skin, moderately pungent, highly flavored, and fibrous; 'Sierra-Leone' with slender rhizomes, buff skin, pungent, with good flavor. Collections are also available from Nepal, Nigeria, USA, New Zealand, and Fiji. The germplasm is maintained as clonal repositories.

Ginger is location specific and the agroclimatic conditions have a great role in creating variability in the qualitative as well as in the quantitative attributes. The crop improvement in ginger is aimed at developing high-yielding cultivars with wide adoption, high-quality parameters (oil and oleoresins), and low fiber, besides resistant to major pests and diseases. The main approach to crop improvement is by selection, with some mutation breeding and polyploidy breeding. Each location has its own high-yielding cultivars (**Figure 11**).

Ginger is propagated vegetatively using rhizome pieces with at least two growing buds. The seed rhizomes from the previous harvest are to be stored properly in pits under shade in layers along with dry sand or sawdust to provide adequate aeration for better germination. Ginger is planted either on raised beds of approximately 1-m width and convenient length or in ridges and furrows. Technology for *in-vitro* induction of microrhizomes in ginger for use as planting material is available. Ginger grows well in warm humid climates, from sea level to an altitude of 1500 m above sea level. It can be grown under both rain-fed and irrigated conditions.

Ginger production benefits greatly from applications of organic manure, including compost and farm-yard manure applied at the time of bed preparation, together with applications of Nitrogen, Phosphorus, and Potassium in three split doses. Mulching with green leaves at the time of planting and again at the time of subsequent fertilization is recommended to prevent erosion of soil due to heavy rain. Studies also confirmed that application of green manure; farm-yard manure, and groundnut cake/sesame oil cake/cotton cake are good for boosting yields. Being a soil-exhaustive crop, it is not desirable to grow ginger in the same site year after year.

The crop is ready for harvest 7–9 months after planting when the leaves start drying up. Harvesting is done by carefully uprooting the underground rhizome without causing injury or damage using either manual or mechanical means. The rhizomes are separated from the dried up leaves. For green ginger, the crop is harvested in 5–6 months after planting. For curing, the rhizomes are soaked in water for 6–7 h and washed to remove soil particles, then rubbed well, the outer skin removed, dried in sun for a week, and then stored in a cool and dry place. Average yield ranges from 15 to 30 ton ha^{-1}, with the yield of dry ginger being 20–25% of the yield of green ginger, depending on the variety.

Turmeric (*Curcuma longa* L. *Syn. Curcuma domestica* Val.)

Commercial turmeric is the dried underground rhizome of the perennial herb *C. longa* L. (Syn: *C. domestica* Val.) (**Figure 12**). Turmeric is used for medicinal and culinary purposes and also as a cosmetic and a natural dye. Turmeric is also credited with religious and magical rites in India and certain Southeast Asian countries. It is geographically distributed in Cambodia, China, India, Indonesia, Lao People's Democratic Republic, Madagascar, Malaysia, the Philippines, and Vietnam. It is extensively cultivated in China, India, Indonesia, and Thailand and throughout the tropics, including tropical regions of Africa, South America, and Australia. The major items of export are dry rhizome and powder. India is the single largest producer, consumer, and exporter of turmeric in the world (Purseglove *et al.*, 1981; Ravindran *et al.*, 2007; Nirmal Babu *et al.*, 2012b). The major markets are USA, Iran, Japan, UK, Bangladesh, Sri Lanka, South Africa, Germany, and the Netherlands.

The past few decades have witnessed extensive research interests worldwide in the biological activity of turmeric and its compounds. Thus, turmeric is gaining importance all over the world as a cure to combat a variety of human ailments because of its antiinflammatory, hypocholesterolemic, choleratic, antimicrobial, antirheumatic, antifibrotic, antivenomous, antiviral, antidiabetic, antihepatotoxic, antioxidant, and anticancerous properties as well as insect repellent activity (Chempakam and Parthasarathy, 2008). The rhizomes contain curcuminoids (2.5–6%) and are responsible for the yellow color. Curcumin (diferuloylmethane) comprises curcumin I (curcumin), curcumin II (demethoxycurcumin), and curcumin III (bisdemethoxycurcumin), which are found to be natural antioxidants. A new curcuminoid, cyclocurcumin, has been isolated from a nematocidally active fraction of turmeric. The fresh rhizomes also contain two new natural phenolics with antioxidant and antiinflammatory activities, and also two new pigments. The essential oil (5.8%) obtained by steam distillation of rhizomes has α-phellandrene (1%), sabinene (0.6%), cineol (1%), borneol (0.5%), zingiberene (25%), and sesquiterpenes (53%).

Turmeric grows well in the tropics of Asia, Africa, and Australia from sea level to an altitude of 2000 m above sea level (Ravindran *et al.*, 2007; Skornickova *et al.*, 2010; Skornickova *et al.*, 2007). Many species of *Curcuma* are economically valuable, and different species are cultivated in different countries. The country of origin of cultivated turmeric (*C. longa*) is presumed to be Southeast Asia.

Turmeric is an erect perennial herb with underground rhizomes but is grown as an annual under cultivation. Rhizomes are fleshy at the base of each shoot and consist of a mother rhizome ringed with the bases of old scale leaves bearing a succession of horizontal or curved rhizomes known as primary, secondary, and tertiary fingers, the whole forming a dense clump (Figure 12). The rhizomes show a deep orange-colored inner core and yellowish orange on the outer side and are rich in curcumin. The inflorescence is terminal and borne in between the leaf sheaths and are pale yellow. Fruiting is rare.

Flowering in turmeric takes place between 109 and 155 days after planting when mother rhizomes or bigger primary rhizomes are planted and depend on the cultivars, climatic conditions, and cultivation practices. Turmeric is a triploid with a chromosome number of $2n = 63$, 84 (Holttum, 1950; Nazeem *et al.*, 1993; Ramachandran, 1969; Nambiar *et al.*, 1982).

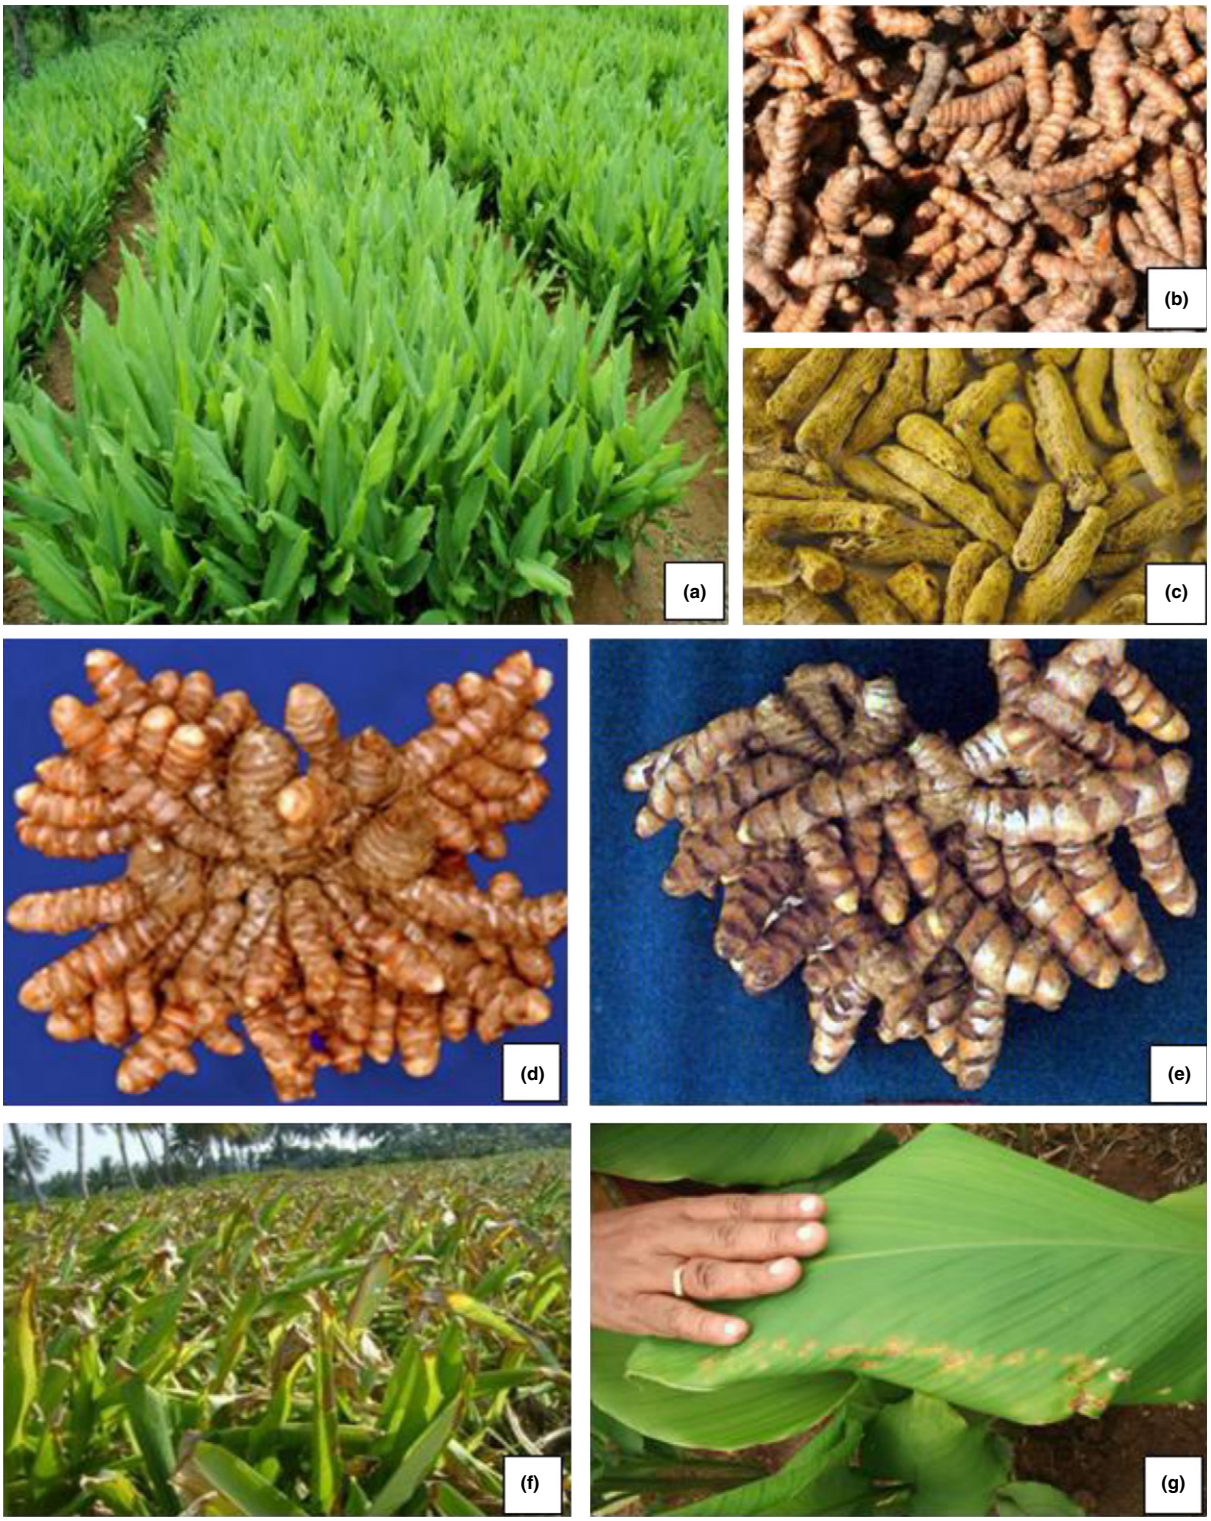

Figure 12 Turmeric (a) field view; (b) fresh primary rhizomes of turmeric; (c) dried and polished turmeric; (d) high-yielding turmeric variety 'Kedaram'; (e) high-yielding rhizome-rot-tolerant short-duration variety 'Suguna'; (f) leaf blotch disease; and (g) leaf spot disease.

The genus *Curcuma* consists of more than 117 species distributed chiefly in South and Southeast Asia of which approximately 40 species are reported from India. In addition to *C. longa*, the other economically important species of the genus are *Curcuma aromatica*, used in medicine and in toiletry articles; *Curcuma kwangsiensis*, *Curcuma ochrorhiza*, *Curcuma pierreana*, *Curcuma zedoaria*, and *Curcuma caesia* used in folk medicines of the South and Southeast Asian nations; *Curcuma*

alismatifolia, *Curcuma elata*, and *Curcuma roscoeana* with floricultural importance; *Curcuma amada* (mango ginger) used as medicine and in a variety of culinary preparations, pickles, and salads; and *C. zedoaria*, *Curcuma pseudomontana*, *Curcuma montana*, *Curcuma angustifolia*, *Curcuma rubescens*, *Curcuma haritha*, and *Curcuma caulina* all used in manufacturing arrowroot powder. The other species of minor importance are *Curcuma purpurascens*, *Curcuma mangga*, *Curcuma heyneana*, *Curcuma zanthorrhiza*, *Curcuma phaeocaulis*, and *Curcuma petiolata* (Skornickova *et al.*, 2007).

Though vegetatively propagated because of rare seed set, there is considerable variability in cultivated turmeric. More than 70 popular turmeric types belonging to both *C. longa* and *C. aromatic* are under cultivation in India. India has good diversity in turmeric cultivars, and a germplasm collection of more than 2000 accessions are maintained in clonal repositories. Wide variability exists among the cultivars with respect to growth parameters, yield attributes, resistance to biotic and abiotic stresses, and quality characters (Govindarajan, 1980; Mohanty, 1979; Ratnambal *et al.*, 1986; Rao *et al.*, 1975; Ravindran *et al.*, 2007). Crop-improvement programs on turmeric in India have been limited to identifying superior turmeric genotypes with high yield, high dry recovery, and high curcumin content. Mutation breeding has also been used; of 24 improved varieties of turmeric (Figure 20) four are induced mutants.

Turmeric is propagated vegetatively through rhizome bits with one or two buds, using mother and finger rhizomes with the larger, rhizomes promoting greater seedling vigor, earlier growth, and higher yield (Rao *et al.*, 2006). Micropropagation and microtuber technology is also available for large-scale multiplication of pathogen-free planting materials (Nirmal Babu *et al.*, 2007). Planting is done in raised beds or ridges with the onset of rains under either rain-fed or irrigated conditions. Turmeric is cultivated either as a single crop or intercropped with other crops, such as maize, castor, and also among coconut plants for increased and diversified income. It grows well in warm humid climates and is widely grown in the tropics of Asia, Africa, and Australia from sea level to an altitude of 2000 m above sea level.

Turmeric can neither stand water logging nor drought and hence is grown under irrigation in major producing areas. It emerges and grows well under partial shade and hence it is recommended as an intercrop in coconut and arecanut gardens. Mixed cropping is also practiced with short-duration crops, such as bhindi, small onion, black gram, green gram, french bean, soybean, or horse gram. It is a heavy feeder and requires a higher level of nutrients and responds well to large quantities of organic manures in the form of farm-yard manure, oil cakes, and green leaves (mulch) (Rethinam *et al.*, 1994).

Turmeric is usually harvested 6–9 months after planting depending on the cultivar, location, and irrigation facilities. Short-duration cultivars mature in 6–7 months, medium-duration cultivars in 7–8 months and long-duration cultivars in 8–9 months. Processing of turmeric consists of cleaning, boiling, drying, polishing, and coloring of raw turmeric rhizomes. Boiling (for 45–60 min) is done to kill the cells as well as to get uniform color throughout the rhizome. Use of sodium bicarbonate in the boiling water (0.1%) gives a deeper color to the final product.

Vanilla (*Vanilla planifolia* Andrews, *Syn. Vanilla fragrans* Salisb.)

Vanilla (Figure 13) is the natural source of the natural flavor compound vanillin, which is the world's most popular flavor. A lower-quality vanilla is obtained from *Vanilla pompano* (Pompan vanilla) and *Vanilla tahitensis* (Tahiti vanilla). It is indigenous to Mexico and Central America and is cultivated in many parts of the world. The main producers are Madagascar, Mexico, Solomon Islands, Indonesia, Seychelles, and Reunion Islands, and the major importing countries are USA, Canada, France, Germany, Japan, Switzerland, UK, Netherlands, Ireland, Denmark, Saudi Arabia, Botswana, Australia, and other European Union countries. Vanilla beans are used for flavoring numerous sweetened foods. Only a small portion of vanilla beans are consumed directly with almost 95% of the beans processed into vanilla extract. The dairy industry is the largest consumer.

Vanilla is a climbing orchid having a stout and succulent green stem and leaves (Figure 13). When the aerial velamin roots reach soil they grow as normal roots and spread in the humus layer. Flowers are large, pale greenish yellow, have short stalks, mature from base to the apex, and last only for a day. Owing to the presence of the rostellum, natural self-pollination is generally impossible. Fruits (capsules, commonly called the beans) contain thousands of minute seeds that are liberated at maturity by longitudinal splitting of the capsule. Under cultivation, the capsules are harvested before they are fully ripe. The seeds do not germinate under natural conditions. Vanillin is extracted from cured beans and is used for flavoring ice creams, chocolate, beverages, cakes, puddings, custards, etc.

Efforts toward crop improvement are confined to the selection of genotypes that perform well under local conditions. Interspecific hybridization is being attempted to bring disease and pest resistance from wild to cultivated vanilla (Minoo *et al.*, 2006a,b, 2008, 2010).

Vanilla is commercially propagated vegetatively through stem cuttings collected from vigorously growing healthy plants. For direct planting in the field, usually 60–120 cm-long cuttings each with 10–20 nods are used as planting material, using extreme care to avoid virus-infected plants. Fresh cuttings after collection should be kept under shade for a week before planting. Such a partial desiccation is essential for good rooting. Micropropagation technology is also available for commercial multiplication of vanilla (Minoo and Nirmal Babu, 2009; Minoo *et al.*, 2010). Being a climber, vanilla requires a standard for support, usually a trellis or low branches of support trees. *Gliricidia maculata*, *Plumaria alba*, *Casuarina equisetifolia*, Mulberry, *Erythrina lithosperma* are used as support trees.

Vanilla grows well in tropical warm humid climates and can be grown between 10° and 20° North and South latitudes from sea level to more than 1000 m above sea level, at temperatures ranging from 25 to 32 °C (average 27 °C). A dry period of approximately 2 months just before flowering is necessary to restrict vegetative growth and induce flowering. Vanilla is a shallow-rooted surface feeder with root growth confined to the decayed organic matter (humus layer) applied around the plant base. A thick layer of humus is required for

Figure 13 Vanilla (a) vine with beans; (b) flowers; (c) processed vanilla beans; (d) *Phytophthora* bunch infection; (e) Fusarium rot; (f) blight; (g) wilt; and (h) virus-affected vines.

its proper growth. Vanilla requires partial shade as leaves get scorched in direct sunlight.

Under good management practice, vanilla flowers by the third year after planting, but it depends on the length and physiology of the original cutting used for planting. The flowering season is from October to March depending on the climate and takes approximately 45–60 days from initiation of inflorescence to flower opening. The flowers begin to open during midnight and last only from early morning to late evening. Natural pollination of vanilla only occurs in the place of origin – Mexico. The natural pollinators are *Melapona* bees and humming birds. Elsewhere in the world commercial fruit production is through hand pollination. A trained worker can pollinate approximately 1000 flowers a day with more than 80% success. It is advisable to pollinate only the first produced 8–10 flowers in a bunch and only 10–12 inflorescences in a vine to get beans of good size.

Stem rot caused by *Fusarium oxysporum* and bunch rot caused by *Phytophthora meadii* (**Figure 13**) and viral diseases are the major production constraints (Sarma *et al.*, 2010).

Vanilla beans take 9–11 months to reach full maturity after flowering. Delay in harvesting leads to splitting of beans and scattering of the seeds. The harvested beans are 'killed' by immersion in hot water at 63–65 °C for 3 min to initiate the enzymatic action that leads to the formation of vanillin. The hot beans are then covered in a blanket and stored in wooden boxes, a process called sweating. The beans are then dried in closed boxes for approximately 3 months at ambient temperature (30–40 °C) until the beans have reached approximately one-third of the original weight and developed various fragrance substances (Sudharsan, 2002). Beans stored at lower temperatures lead to 'frosting' (deposition of vanilla crystals on the beans). The important attributes of cured vanilla beans for grading purposes are length of beans, aroma, and color flexibility, luster and free from mold and insect infestation. Properly cured beans will yield 2–2.5% vanillin.

Tree Spices

There are 17 trees used as sources of spices and grown in humid tropical forests of India, South and Southeast Asia, Australia, Pacific Islands, and Tropical America. Among them cinnamon, clove, nutmeg, tamarind, garcinia/kokam, curry leaf, and allspice are the most important (Nybe *et al.*, 2007).

Cinnamon (*Cinnamomum verum* Bercht and Presl. Syn. *Cinnamomum zeylanicum*, Blume)

Cinnamon (**Figures 14(a)** and **(b)**) is obtained from various sources, including *C. cassia* (syn. *C. aromaticum*) (Chinese cassia), *C. burmannii* (Indonesian cassia), *C. loureirii* (Saigin cassia), and *C. tamala* (Indian bay leaf). The genus, a native of Southwestern tropical India and Sri Lanka, consist of more than 250 species distributed in Southeast Asia, China, and Australia. Seychelles and Malagay Republic are the major cinnamon-producing countries besides Sri Lanka.

True cinnamon comes from the dried bark of *C. verum*. In addition, oil can be obtained from the bark (bark oil), leaves (leaf oil), roots (root bark oil), and seeds (seed oil). The main constituent of leaf oil is eugenol (75–80%) and that of bark oil is cinnamaldehyde (65%). The bark, oil, and oleoresin are the economically important products. Bark either as a small piece or as powder is extensively used as spice or condiment in food and confectionary. In the ground form, it is used in curry powders and in the preparation of various preserves. It is also used in the manufacture of soaps, dental preparations, and perfumes.

Cinnamon is said to have carminative, astringent, simulative, and antiseptic properties. It is prescribed in powder and infusion but is usually combined with other medicines and claimed to check vomiting and relieve flatulence and gastric disabilities. It has a high germicidal and fungicidal activity but the irritant nature prevents its use as such.

Cinnamomum verum is a medium-sized evergreen tree, reaching a height of 15–20 m in 25–30 years, but generally coppiced for the enhancement of side shoots. The cinnamon germplasm collection in India has 500 accessions, 35 wild species, and 14 exotic accessions. There is wide variability in the cinnamon germplasm for various yield-attributing characters, such as number of peeler shoots per plant, plant height, plant girth, and tree spread, and quality characters. Crop improvement for the production of cinnamon is confined to selection and popularization of elite types from the germplasm for better regeneration capacity, yield of dry bark, and quality of the bark (Haldankar *et al.*, 1994; Krishnamoorthy *et al.*, 1996; Ravindran *et al.*, 2004). So far, seven high-yielding improved selections were released for cultivation from India.

Cinnamon is commonly propagated through seeds extracted from ripe fruits from mother trees with desirable characters, such as smooth bark, erect stem, easy pealing of bark, vigorous growth, free from pests and diseases, and having good qualities, such as sweetness, pungency, and flavor. The seeds are sown immediately after collection; otherwise viability is reduced. Under normal conditions, seeds germinate within 20 days. Seedlings are transplanted from beds to polythene bags for better growth. Ten- to twelve-month-old seedlings are suitable for planting (Krishnamoorthy and Rema,1988). Cinnamon is also propagated using hard and semihard wood cuttings.

Cinnamon is a hardy plant that tolerates a wide range of climatic conditions. The crop performs well from 300 to 350 m above sea level and thrives up to 1000 m. It flourishes in places with an annual rainfall of 150–250 cm with an average temperature of 27 °C. A hot and moist climate is highly suited for its cultivation but prolonged spells of dry weather are not conducive for its growth. In general, cinnamon is free from serious pests and diseases.

Coppicing is practiced from the fourth or fifth year depending on the availability of peeler shoots. Stems are cut during rains to facilitate peeling. Best time for peeling (**Figure 14(b)**) is when new flushes and leaves are hardened after a rainy season. The side shoots are also cut so that the plant assumes the shape of a low bush and a bunch of canes suitable for peeling are subsequently available. The best quality is obtained from the thin bark of shoots in the center

Figure 14 Tree spices (a) cinnamon flowering branches; (b) harvesting of cinnamon quills and bark chippings (inset); (c) clove flower buds ready for harvest and dried flower buds (inset); (d) nutmeg fruits ready for harvest; (e) variability in nutmeg fruit, mace (including yellow mace and nut characters); (f) nutmeg nuts; (g) nutmeg aril; (h) anthracnose (*Colletotrichum* sp.) in nutmeg leaves; and (i) thread blight in nutmeg.

from the middle portion of shoots. Fully developed cinnamon shoots of 1.5–3.0 cm diameter harvested during the rainy season gives good quality bark and high yield (Pruthy *et al.*, 1978). After scraping the outer skin, the peeling of the bark is done carefully by piercing the bark with a sharp knife. The tube-like barks thus obtained in lengths of 6–8 in. are placed one inside the other to form a tube of length 1 m called quills and dried. Barks that cannot be taken out like tubes are called

'quillings' and the scraped pieces are called 'featherings.' Approximately 70–100 kg of quills and 30 kg of quillings and featherings are obtained from an acre of cinnamon after 4 years.

Clove (*Syzygium aromaticum* (L) Merr. and Perry)

The clove of commerce is the dried, unopened flower buds (Figure 14(c)) of the evergreen tree, *Syzygium aromaticum* (L), of the family Myrtaceae. It is native to the Moluccas. The major clove-producing countries are Indonesia, Zanzibar, and Madagascar. The importing countries are India, USA, Germany, France, and Singapore. The world production is estimated to be 63 700 ton and Indonesia alone accounts for 66% of the world production.

India grows two morphological variants of clove, one with bolder flower buds (king clove) and the other a smaller spreading plant type (dwarf clove). Crop improvement in clove is confined to selection of high-yielding mother cloves. Propagation of these trees is through seeds. The clove is a slender, evergreen tree reaching a height of 10–15 m. The fruit is a one-seeded drupe popularly known as mother clove. It contains one oblong seed 1.5 cm long. Clove flowers are bisexual and inbreeding is common. The variability in clove is very limited, with the present-day population in India reported to have been originated from a few trees with a narrow genetic base originally introduced into India. Self-pollination also limits the scope for variability.

Propagation of clove is through seeds collected from healthy regular-bearing trees. Seed viability is short and hence they are to be sown immediately after collection. One- to two-year-old seedlings are suited for main field planting. Clove requires a humid climate and grows at 600–1000 m above sea level with a rainfall of 1500–2000 mm and a mean temperature of 20–30° C. Clove is a shade-loving plant and is successfully cultivated under coconut plantations aged more than 20 years.

Clove trees start flowering from the forth year after planting under good management conditions. Full-bearing stage is reached only after 15 years. Flowering season ranges from October to December. Flower buds are harvested when they turn pink. The harvested flower buds are separated from the clusters by hand and are dried for 4–5 days. On an average 3–4 kg of dried buds can be harvested from 15-year-old clove trees. The dried buds yield 14–21% oil, which contains 70–90% eugenol and 5–12% eugenol acetate.

Nutmeg (*Myristica fragrans* Houtt.)

Nutmeg (Figures 14(d)–(i)) includes two distinct spices: nutmeg (seed) and mace (aril). Native of Indonesia (Moluccas Islands), the nutmeg tree grows there abundantly and is now naturalized in West Indies, Sri Lanka, India, Philippines, Tropical America, and Pacific Islands. It is also grown in a small scale in Sri Lanka, Trinidad, China, India, Tobago, Zanzibar, and Mauritius.

Nutmeg is an evergreen aromatic tree usually 10–20 m tall with spreading branches. The fruit is pyriform and yellow in color (Figure 14(d)). The pericarp is fleshy when the fruit matures; it splits into two, exposing the scarlet-colored net like aril covering the dark brown seed (Purseglove *et al.*, 1981; Verghese, 2000; Krishnamoorthy, 2000). The principal constituents of nutmeg are fixed oil (fat), volatile oil, and starch. The flavor and therapeutic action are due to the volatile oil whose content varies from 6% to 16% based on the origin and quality of nutmeg (Lewis *et al.*, 1966). Nutmeg fat contains eight fatty acids, the most important of them being myristic acid. Nutmeg and mace are used as a stimulant, carminative, astringent, aphrodisiac, and hallucinogen. Oil of nutmeg or mace is employed for flavoring food products and liquors, soaps, tobacco, dental creams, and perfumery products. The fleshy pericarp of the fruit is used for making pickles and jelly.

The genus *Myristica* consists of approximately 120 species. A high amount of variability has been reported in growth rate, productivity, size and shape of the leaf, flower size and shape and size of the fruit and nut, and the amount of mace in nutmeg (Krishnamoorthy and Rema, 1991; Haldankar *et al.*, 1999). Crop improvement in nutmeg is confined to selection and multiplication of elite lines. So far, three improved varieties were released in nutmeg.

The general method of propagation of nutmeg is through seeds collected from regular-bearing and high-yielding trees. The seeds have low viability and hence are to be sown immediately after collection. Germination commences from about the 40th day and lasts for up to 90 days after sowing. The germinated sprouts must be transferred to polythene bags (30 cm×15 cm) containing a potting mixture. After 1 year in a nursery the seedlings can be field planted. Nutmeg, being a dioecious crop, requires that the proper ratio of female and male plants (10:1) be maintained in the plantation. Vegetative propagation techniques, such as approach grafting, softwood grafting, epicotyl grafting, budding, and top working in nutmeg are commonly used, with epicotyls grafting being the best (Mathew, 1985; Haldankar *et al.*, 1999; Rema *et al.*, 2000).

Nutmeg requires a hot humid climate with no pronounced dry season and is a shade-loving plant. It can be grown up to approximately 900 m above sea level. In India, nutmeg is planted as an intercrop in coconut plantations. Fruiting commences from 6 to 9 years depending on the climate and planting materials used. Optimum productivity is attained in approximately 15 years. Fruits are collected periodically from the tree by hand or with hooked sticks or allowed to fall naturally on the ground. All three parts of the fruit, viz. the pericarp, aril (mace), and seed (nutmeg) are separated carefully and sun dried or are dried by mechanical means. Aflatoxin is a serious post-harvest problem in the mace and nuts.

Garcinia (*Garcinia cambogia* Desr (Syn. *Garcinia gummi-gutta, L.*) and Kokam (*Garcinia indica* Chiosy)

Garcinia (Figure 15) and Kokam are two potential underexploited tree spices, currently gaining much agricultural, commercial, industrial, and medicinal importance. Cambodge, the product of commerce, is the dried pericarp lobe used in the preparation of Indian dishes. Fruits are edible but too acidic to be eaten raw. They are valued for the processed and dried pericarp used as condiment for flavoring curries, as a very popular spice used in cooking, as a major ingredient in

Figure 15 The spice tree, *G. cambogia* (left); dried rinds of comboge (center); ripe fruits of *G. indica* (right).

many dishes as a substitute for tamarind. They are also used in the pharmaceutical industry as a source of hydroxy citric acid (HCA), an antiobesity compound, and as an ingredient in herbal medicines. The reddish rind of kokum is used for the preparation of a refreshing, attractive drink. The fruit has excellent therapeutic value against obesity and is used for ailments, such as rheumatism, rickets, and enlargement of spleen. The fruit, being rich in acids, also possesses antiseptic properties. The fruit rind of kokum after drying and mixing with sugar sirup is used to control hyperacidity. Garcinia rind is the richest known natural source of HCA, the derivatives of which are potent metabolic regulators of obesity. The unique acid lowers the blood lipids, such as cholesterol and triglycerides, by triggering fatty acid oxidation in the liver via thermogenesis.

Garcinia and Kokam are both found naturally in the Western Ghats and in the evergreen forests of North Eastern India and Southeast Asia. In India, Garcinia has two centers of distribution: the Western Ghats and the North East region. *G. cambogia* and *G. indica* occur in the Western Ghats of Kerala.

Garcinia is a moderate sized (18–20 m) evergreen tree with an oval-shaped crown. It has separate male and bisexual trees and it is a cross-pollinated species. Flowers are solitary or in groups of 2–3 in bisexual trees and in clusters of 3–5 in male trees. Fruit are ovoid, weighing 50–180 g, and are yellow or reddish yellow at maturity. Kokam is a small slender evergreen tree growing up to 18 m tall with drooping branches that attain a pyramidal shape. It is a dioecious tree with spherical fruit each having 5–8 seeds compressed in an acid pulp.

Immediately after harvest the fruit is cut into two halves. Seeds along with the pulpy mass are removed and the cleaned rind is either sun-dried or smoke-dried for 3–7 days to keep a moisture level of 15–20%. Cambodge and kokam concentrate are produced from dried or fresh rind.

Garcinia is mostly collected from the wild or from home gardens; commercial cultivation of garcinia is yet to pick up. Propagation is through seeds with the seedlings segregated into productive bisexual and unproductive male trees.

Figure 16 The fruit of tamarind.

Vegetative propagation through softwood grafting/side grafting is commonly practiced. A hardy tropical tree crop, it can be grown in tropical and subtropical climates from seashore to an elevation of 1200 m. It is adaptable to a wide range of climatic and soil conditions.

Tamarind (*Tamarindus indica* Linn.)

Tamarind (Figure 16) is one of the most important tree spices. Originated in Madagascar, it is now cultivated in India, Thailand, Mexico, the Middle East, Africa, Southeast Asia, the Caribbean, Bangladesh, Myanmar, Malaysia, Sri Lanka, Central Africa, Australia, and Central and South America. It is one of the most common trees in most parts of India and the source of one of the most commonly used spices in the Indian kitchen. The fruit pulp, the useful part of tamarind, is a rich source of tartaric and ascorbic acids. India exports tamarind pulp to the UK, Iraq, Oman, Germany, and some countries in the Pacific.

Tamarind is a slow-growing evergreen tree with a height of up to 25 m. It prefers a warm climate, withstands drought, but is sensitive to frost. The tree flowers between April and June and the fruit ripens by winter. Tamarind flowers are bisexual and produced in small terminal racemes. Pollination is by bees. Fruit is a pod, 10–15 cm long and 2–3 cm wide, 3–10 seeds each, and is strap shaped. The pods begin to ripen from February to April. Annual fresh yield is in the range of 150–500 kg per tree.

All the plantations in India originated from seedlings and hence there is immense scope for selection of desirable traits. A germplasm bank with more than 500 collections is maintained in India. Twelve elite types were short listed from the germplasm for multiplication and distribution. The variety Periakulam-1, an early-bearing line, was released for cultivation in India. Two more high-yielding cultivars, viz. Prathisthan and No. 263 selection, were also released. In Thailand, a very sweet tamarind type is reported to be grown. Local cultivars, such as Cumbum or Lower Camp and Urigam, are popular in the Cumbum area of Tamil Nadu, India. On the basis of color and taste of pulp, tamarind is classified as the sweet and red types. The red-fleshed type is known as 'yogeswari.'

Tamarind is a highly adaptive evergreen tree that can thrive well at temperatures in the range of 30–40 °C and an annual rain fall of 500–2000 mm. Tamarind is suited for growing in semiarid areas. It does well in poor soils. In India, tamarind grows well in almost all areas, except under high elevations. It can be propagated by seed or clonally. Approach grafting and softwood grafting are also used in addition to patch budding for large-scale multiplication.

Fruits contain approximately 30% pulp, 40% seed, and 30% hull. When fruits are ripe, the pulp is rust-colored and its water content is approximately 38%. It is rich in pectin and reducing sugars and contains a significant amount of organic acids, 98% of which is tartaric acid. The main flavor compound of the pulp is 2-acetylfuran.

The fruits are harvested when fully ripe and the fruit shell is almost dry. The ripe fruits are shelled, the seeds and pulp are removed, and the separated pulp is dried for a day or two in sun and then mixed with approximately 10% of common salt. The pulp has a sharp, sweet, sour, fruity taste, and a sweetish brown aroma. The fruit pulp is the chief agent for sour curries, sauces, chutneys, and certain beverages throughout the greater part of India. Tamarind fruit is reported to be used as a raw material for the preparation of wine-like beverages.

Curry Leaf (*Murraya koenigii* Linn.)

Curry leaf (Figure 17) is cultivated for its aromatic leaves and is widely used in Asian cooking as an essential flavoring in most Indian food preparations. Leaves, roots, and seeds of the plant all contain the active principles and essential oil of medical value and extensively used in many Ayurvedic preparations. Leaves are used internally against dysentery, diarrhea, and also to check vomiting. Leaf paste is applied externally for curing bruises and bites of poisonous animals.

Thought to have originated in India and Sri Lanka, *M. koenigii* is grown from South and East Asia to Australia. It occurs widely in India, Myanmar, Java, Laos, Bangladesh, Madagascar, Sri Lanka, Malaysia, and the Pacific Islands. It also

Figure 17 Fresh curry leaves.

grows wild and is found almost throughout India up to an altitude of 1500 m, including in the forest along the foot of Himalayas to Sikkim and Assam, Chitagong, upper and lower Burma, and Andaman.

A small tree reaching a height of 6–8 m under cultivation, it is maintained as a bush by periodical coppicing. Flowers are white and fragrant; berries are purplish-black when mature. The stem and branches are covered with brownish bark and have a pleasant aroma but pungent taste. Curry leaf plants are broadly classified into the broad-leaved and narrow-leaved types. The broad-leaved varieties are used for commercial cultivation, whereas narrow-leaved varieties are grown for home use.

Curry leaf is propagated by its seeds that germinate in 3–4 weeks under partial shade. Seedlings can be raised in individual polybags, which after 1 year can be directly planted in the field. Curry leaf can also be propagated by root suckers. Being a hardy crop, curry leaf grows under varying climatic and soil conditions, including at altitudes of 60–1200 m above sea level and at temperatures of 16–37 °C.

Commercial harvesting of leaves can start at 3-month intervals when the trees are of 3–4 years old. The average yield is approximately 20 ton ha^{-1}. Fresh leaves contain up to 2.6% essential oil. The important aroma components are β-caryophyllene, β-gurjunene, β-elemene, β-phellandrene, β-thujene, α-selinene, β-bisabolene, limonene, β-*trans*-ocimene, and β-cadinene. Fresh leaves on steam distillation yield approximately 2.6% of a volatile oil (curry leaf oil). The oil contains DL-α-phellandrene, D-sabinene, D-α-pinene, dipentene, D-α-terpineol, caryophyllene, safrol, cadinene, cadinol, lauric acid, and palmitic acid.

Pimento (Allspice) (*Pimenta dioica* L. Merr.)

Pimento of commerce is the dried unripe fruits of *P. dioica* L. Merr., an evergreen tree that grows to a height of 8–12 m and belonging to the family Myrtaceae. Pimento is the major spice of Jamaica contributing 70% of the world's production. It is grown to a certain extent in Mexico, Honduras, Guatemala, Cuba, Haiti, and Costa Rica, besides a few West Indian islands. The dried immature berry combines the odors and flavors of four spices, namely, nutmeg, clove, cinnamon, and black pepper, hence the name 'allspice.' Allspice is an aromatic,

stimulant, digestive, and carminative. Powdered fruits are used against flatulence, dyspepsia, and diarrhea and are used in the preparation of tonics and purgatives. It is used in many culinary preparations, such as soups, sauces, ketchup, pickles, meat, curry powder confectionary, and in liquor as a flavoring.

Allspice is polygamodioecious in nature, which makes it difficult to identify functional male and female trees until they begin to bear fruit. The common method of propagation is by seeds collected from high-yielding and regular-bearing trees. The trees start flowering in 5–6 years under good management. Fully developed greenish berries are harvested, dried, and used as spice.

Seed Spices

Coriander, cumin, fennel, and fenugreek are the major seed spices of commerce.

Coriander (*Coriandrum sativum* L.)

Coriander (Figures 18(a)–(d)) is grown extensively in India, Russia, Morocco, Romania, Bulgaria, Mexico, France, Spain, Italy, Holland, Argentina, China, Egypt, North Africa, Hungary, Yugoslavia Poland, Czechoslovakia, Guatemala, USA, Middle

Figure 18 Coriander and cumin (a) coriander seed; (b) coriander field view; (c) powdery mildew on coriander foliage; (d) coriander as an intercrop in young black pepper plantation in Brazil; (e) cumin field view; (f) cumin wilt; and (g) powdery mildew on cumin.

East, and South Asia. India is the major producer where it is cultivated for its leaves and seeds. Malaysia, Singapore, South Africa, UAE, UK, USA, Saudi Arabia, and Indonesia are the major importing countries. It is native to Eastern Mediterranean region and Southern Europe and is widespread as both cultivated and naturalized weedy species throughout the warmer regions of the world.

Coriander is a short-season annual, semierect to erect herb cultivated for its dried aromatic fruits and tender leaves. The fruit consists of two mericarps, almost round, 3–4 mm in diameter. The leaves have a totally different flavor and are used fresh or dried in cooking. All parts of the plant-tender stem, leaves, flowers, and fruits have characteristic pleasant aromatic odor. The seed has a very pleasant odor and taste due to the presence of essential oil varying from 0.1% to 1.7% on dry weight basis. The composition of oil varies depending on the country of origin and climatic conditions where it is grown. The content of essential oil is generally more when grown in colder regions and at higher altitudes. Thus, the volatile oil content is higher in the Russian and European coriander varieties and the fruits are smaller than the Indian coriander. The Russian varieties have small spherical fruits and are considered superior to Indian and Moroccan due to their higher essential oil content. The leaf contains approximately 4% volatiles on a wet leaf basis. The principal component of the oil is D-linalool, also known as coriandrol (60–70%), an important starting material for the production of a variety of aroma chemicals. Other compounds present are D-pinenes, terpinenes, geraniol, and borneol.

The crop-improvement programs in coriander are essentially selections from open pollinated or controlled crosses. Approximately 24 improved cultivars were released for cultivation in India. A few tolerant/resistant lines against wilt and stem gall have been developed. A dry and moderately cool weather condition favors high seed formation as well as quality of the produce. Sowing is done by broadcasting on plowed and leveled land or using seed drills. Coriander is grown both as a rain-fed and irrigated crop. The crop is ready for harvest in approximately 90–120 days after sowing for grains and 40 days for greens depending on the varieties and growing season. Leaf plucking to the extent of 50% of the foliage, 60–75 days after sowing, gives an economical return. Fruits ripen progressively on the plant; harvesting is done when fruits are fully mature, i.e., when the green color has changed slightly to yellow. Bundles are dried under shade to avoid breakage of seeds and loss of volatile oil. After drying, plants are mildly threshed and grains are separated. Seeds can shatter if harvesting is delayed (Singhania *et al.*, 2005).

Cumin (*Cuminum cyminum* L.)

Cumin (**Figures 18(e)–(g)**) of commerce is the dried fruit of the annual herb, *C. cyminum* L., and belonging to the family Apiaceae. Cumin seeds are small, elongated, yellowish brown, aromatic, and spicy, having a bitter taste and strong flavor. The main ingredient of cumin is cuminaldehyde (cuminic aldehyde) present in the volatile oil. Cumin finds worldwide use in foods, beverages, liquors, medicines, toiletries, and perfumery. Seeds are extensively used in a variety of culinary preparations. Cumin is also an important ingredient of curry powder and spice mixture; for flavoring soups, vegetables, sausages, pickles, and a variety of curries; and for preparing cold/soft drinks like Jal-jeera. The aromatic oil is used for flavoring curries, liquors, cordials, and also in perfumery. It is also used as a fungicide, insecticide, and as a veterinary medicine.

Cumin is a small, slender, herbaceous bushy annual plant with a much branched stem and long finely dissected narrow, deep-green leaves. The plant grows to a height of approximately 15–60 cm, with many branches. Flowers are small, rose, or white. The plant comes to bearing in 60–90 days from sowing. The elongated grayish (yellowish brown) bristly fruit (schizocarp) are approximately 6 mm long, tapering toward both ends, laterally compressed with a short stalk. Seeds contain 2–5% volatile oil of which 40–65% is cuminaldehyde.

Cumin is grown in Egypt, Syria, Turkistan and in the Eastern Mediterranean region, Iran, China, Mexico, Indonesia, Japan, Pakistan, Italy, Afghanistan, Germany, whereas UAE, UK, USA, Singapore, Nepal, Malaysia, Japan, Bangladesh, and Brazil are the major importers. India is the largest producer.

Cumin is mainly a tropical plant and thrives well in tropical and subtropical climates. A moderately cool dry climate is best for cumin cultivation and hence it is grown as a winter crop. The crop matures in 130–150 days after sowing when the leaves turn yellow and is ready for harvesting by the beginning of summer. The crop is vulnerable to frost damage. Five high-yielding high-quality cultivars have been released for cultivation in India (Patel *et al.*, 2005).

Harvesting, usually done in the morning hours to avoid shedding losses, is by uprooting the whole plant or cutting the plant with a sickle. The harvested plants are bundled and stacked for 2 days and subsequently spread out on the threshing floor to dry in the sun. Threshing is either by beating with stick or by rubbing the plants with hands in to gunny bags. Seeds are cleaned by mechanical winnowing, and are packed and stored under ambient conditions.

Fennel (*Foeniculam vulgare* Miller)

Fennel (**Figures 19(a)–(b)**), the dried fruit of an aromatic herb, *F. vulgare* Miller, belonging to the family Apiaceae, is a native of Europe and the Mediterranean region and is cultivated in temperate regions around the world. The main fennel-producing countries are India, Egypt, China, Romania, Russia, Germany, France, Italy, Japan, Argentina, USA, Indonesia, and Pakistan. Morocco, Spain, and Southern Europe. The main importing countries are Canada, Malaysia, UAE, UK, Japan, Malaysia, Singapore, Saudi Arabia, USA, Bangladesh, South Africa, Bahrain, and Holland.

The feathery fragrant leaves are used as a herb and the seed as spice. The leaves are also used for garnishing. Fennel seed is used for flavoring meats, vegetable products, fish sauces, soups, salad dressings, stews, breads, pastries, and alcoholic beverages. Fennel contains 1–3% of a volatile oil composed of approximately 50–60% anethole and 20% de-fenchone. Other compounds present in fennel are D-α-pinene, D-α-phellandrene, dipentene, methyl chavicol, feniculum, anisaldehyde,

Figure 19 Fennel and fenugreek (a) field view of fennel; (b) mature seeds of fennel; (c) fenugreek seeds; (d) field view of leafy type of fenugreek; (e) root rot on fenugreek; and (f) powdery mildew on fenugreek foliage.

and anisic acid. The volatile oil of fennel is used in favoring medicines; to scent soaps and perfumes; flavor beverages, baked foods, condiments, ice creams, and liquors and season meats and sausages. Fennel is used in Ayurvedic or domestic medicines. The plant is pleasantly aromatic and used as a potted herb; leaf stalks are used in salads and vegetables (Singhania and Singh, 2005).

Fennel can be grown in all types of well-drained soils except sandy soil. It requires a fairly mild climate and is grown as a cold-weather crop in North India as well as in higher elevations in South India.

When the fruiting umbels turn brown they are ready for harvest. As the umbels do not mature uniformly, several harvests are necessary to maximize yield. For good quality fennel, the umbels should be picked when seed development is completed and before full maturity when seeds start turning yellow. After harvesting, umbels are dried in sunlight for 1–2 days, followed by further drying in shade to retain the color.

For producing the chewing-type fennel, umbels are harvested at 30–40 days after pollination when seed size is just half of fully developed seeds.

Fenugreek (*Trigonella foenum-graecum* L.)

Fenugreek (**Figures 19(c)–(f)**) is the dried seed of a slender annual strongly scented herb, *T. foenum-graecum* L. and belongs to the family Fabaceae. It is a native of Europe and Asia (Eastern Mediterranean) and is now cultivated in India, Pakistan, France, Morocco, Greece, Lebanon, Germany, Argentina, and USA. Bahrain, UAE, Holland, Saudi Arabia, USA, and UK are the major importing countries, whereas Argentina, Algeria, Egypt, France, Moroco, Ethiopia, Lebanon, Australia, and Pakistan are the major producing countries.

The seed has a strong aroma and bitter taste and is used as a spice in the preparation of a variety of dishes and pickles. Fresh green leaves are used as a vegetable and whole plants as fodder. Ground seed is used in curry powders, spice blends, pickling spice, mayonnaise, etc. The seed or extracts are commonly used in sirups, pickles, baked foods, condiments, chewing gums, and meat seasoning and as an emollient and flavoring agent in pharmacy. Diosgenin, an important steroid, is present in seeds. Most of the product is consumed domestically. Because of its high nutritive contents, it is an important ingredient in vegetable dishes. Fresh or dried leaves are widely used in Indian cooking and are often combined with vegetables.

Flowers are small whitish and yellow. The crop flowers in 50 days after sowing and it takes 80–90 days to reach maturity after flowering. Fenugreek grows well in subtropical climates, with a moderately cool climate being required for proper growth and good yield. It is generally grown as irrigated crop (Singhania *et al.*, 2005).

The ground seed has a very strong spicy but bitter flavor. The volatile oil content is extremely odorous and fixed oil has a very bitter taste. The volatile oil content of fenugreek is very small (less than 0.02%). It also contains fixed oils (fat) at 5–7%. They contain the alkaloids trigonelline and choline. It is rich in proteins, minerals, and vitamins.

Introduction

At the time of their discovery in 1981 by Sir Martin Evans and his colleagues at Cambridge University, embryonic stem cells (ESCs) were defined as pluripotential cells that could be maintained in culture and could retain the ability to contribute to all of the somatic lineages and the germline. At the time, the field was aligned with an agricultural interest in splitting embryos at early stages (e.g., 4 and 8 cell embryos) to propagate genetically identical animals (i.e., cloning), a desire to insert specific modifications into the genome of animals and the field of tumorigenesis. The hope of many was that pluripotential cell lines would be found and propagated with the ease of transformed cells derived from tumors. Speculation during this era also predicted that these cell lines would be genetically modified using emerging recombinant DNA technologies. Furthermore, it was the hope of many that whole animals could be derived from these pluripotential cell lines in the same way that whole plants could be propagated from callus tissues.

In spite of enormous effort, very few of the predictions of the 1980s have been realized as they were envisaged. Nevertheless, the objectives of accessing cloning technologies and developing genetic engineering tools have been achieved. The equivalent of murine ESCs has not been found for any other animal but the need for these cell lines has been greatly diminished by the development of somatic cell nuclear transfer (SCNT), which shifted the focus from stem cells to reprogramming of somatic cells.

Murine Embryonic Stem Cells Are the Gold Standard

Murine ESCs remain the gold standard against which all other pluripotential cell lines are measured (Figure 1). They can be maintained in culture for extended periods, they can be genetically modified using a variety of technologies and they will contribute to both somatic tissues and the germline. To date, thousands of mutations have been inserted into the murine germline using a variety of sophisticated genetic engineering approaches. Although most of these mutants have been created to advance biomedical research (e.g., see the Jackson Laboratories and Taconic catalogs), some of these mice have been used to create many of the human therapeutic antibodies marketed in the past decade (Lonberg, 2008).

The Murine Embryonic Stem Cells Phenotype

Although morphology and gene expression are used as surrogates for the ESC phenotype (see Sections Morphology and Culture Conditions for Murine Embryonic Stem Cells; Gene Expression Profile of Murine Embryonic Stem Cells), the ultimate property defining ESCs is their ability to contribute to somatic tissues and the germline following their return to an embryonic environment. In mice, a few ESCs are injected into the inner cell mass to form a G0 chimera comprised of endogenous cells and ESC-derived cells. Ideally, the ratio of endogenous cells to ESC-derived cells should be very low and technologies to entirely eliminate the contribution of the recipient murine embryos have been developed (Nagy *et al.*, 1993). From a theoretical perspective, the recipient embryo serves only to organize the donor ESCs into an embryonic template. Practically, the contribution of ESCs to somatic tissues can be evaluated using visual markers such as coat color or introduced genes such as green fluorescent protein (GFP). Quantitation of the contribution of ESCs to the germline requires mating the G0 chimera to obtain G1 offspring. Typically, the G0 gonad contains both ESC-derived and endogenous sperm or eggs and the ratio of donor-derived to endogenous offspring (i.e., the rate of germline transmission) varies from 0 to 100%. For mice, *in vivo* evaluation of the rate of germline transmission by breeding can be achieved within a few months. However, the long generation times of agriculturally relevant animals makes *in vivo* evaluation of putative ESCs time consuming and expensive. Hence, morphology, behavior of the cells *in vitro*, the culture conditions, and gene expression profiles are used as indirect measures of the ESC phenotype (see Sections Morphology and Culture Conditions for Murine Embryonic Stem Cells; Gene Expression Profile of Murine Embryonic Stem Cells).

Morphology and Culture Conditions for Murine Embryonic Stem Cells

Murine ESCs require the presence of Leukemia Inhibitory Factor (LIF) in the media to maintain ESC morphology and

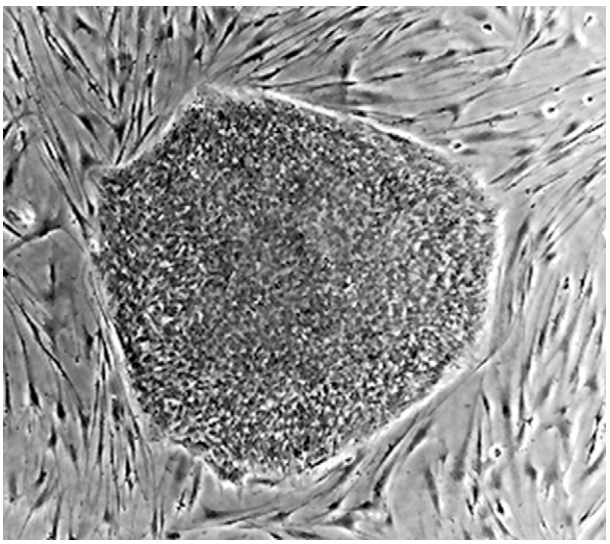

Figure 1 Murine embryonic stem cells growing on a layer of murine embryonic fibroblasts. Reproduced from Adamo, L., García-Cardeña, G., 2011. Directed stem cell differentiation by fluid mechanical forces. Antioxidants and Redox Signaling 15 (5), 1463–1473.

 doi:10.1016/B978-0-444-52512-3.00239-4

functionality. Typically they are cultured in Dulbecco's Modified Eagle's Medium supplemented with 10–20% fetal bovine serum, glutamine, nonessential amino acids, β-mercaptoethanol, and 1000–2000 units of LIF in the presence of a feeder layer comprised of inactivated murine embryonic fibroblasts (see Section Relevant Website). Alternatively, murine ESCs can be grown without feeders on gelatin coated plates. Murine ESCs are small cells attached to the feeder layer with a large nucleus and small amounts of cytoplasm.

Gene Expression Profile of Murine Embryonic Stem Cells

It is self-evident that cells within tissues express genes encoding their specific function and gene expression profiling has been applied by many in an attempt to define the gene expression profile of pluripotential cells. Murine ESCs are distinguished by expression of Nanog, Oct4, Sox2, and telomerase. Expression of these genes, however, does not necessarily confer all of the properties of murine ESCs, even in the mouse (see Section *In Vitro* and *In Vivo* Evaluation of Murine Embryonic Stem Cells). Characterization of the gene expression profile that confers the ability of cells to contribute to both somatic tissues and the germline has been used as a surrogate in the search for ESCs in other animals, but to date, cells with expression profiles that resemble those of murine ESCs have failed to yield practical contributions to either somatic tissues or the germline. These data underscore the empirical nature of the stem cell research which to date, relies primarily on a functional definition to define the phenotype of these cells.

In Vitro and *In Vivo* Evaluation of Murine Embryonic Stem Cells

In the absence of feeder cells or a substitute substrate, murine ESCs form embryoid bodies. These cystic structures differentiate into many different cell types in the somatic lineages and, therefore, provide evidence that the ESCs are pluripotential (Martin, 1981). Putative ESCs can also be evaluated by injection into the peritoneal cavity of mice, where they form teratocarcinomas. Like embryoid bodies, teratocarcinomas include cells from the endoderm, mesoderm, and ectodermal lineages indicating that they are pluripotential. Construction of embryoid bodies and the formation of teratocarcinomas have been employed as surrogates for pluripotency in the evaluation of putative ESCs from other animals. Although embryoid bodies and teratocarcinomas are reasonable surrogates for contributions to the somatic tissues of chimeras, equivalent surrogates for germline transmission in chimeras are not available.

Non-Murine Embryonic Stem Cells

The elusive search for non-murine ESCs may be attributed to their absence during embryogenesis. Although it is clear that ESCs share many of the attributes of inner mass cells in the blastocyst, it remains unclear if ESCs and inner cell mass cells are identical. The murine ESC phenotype might be created by the conditions of the cell culture system or it may be a transient cell type during embryogenesis that is held in a static state *in vitro*. It is also unclear if there is sufficient homology between the inner cell mass of murine and non-murine blastocysts to extrapolate to other species although the failure to find non-rodent ESCs suggests that conditions that support inner cell mass cells in other mammals are different from those that support murine ESCs.

The close phylogenetic relationship between rats and mice suggests that culture conditions supporting murine ESCs might also support isolation and propagation of inner cell mass cells from rats. However, 25 years of empirical tweaking of the culture conditions were required before conditions for the culture of rat ESCs were described (Meek *et al.*, 2010). As the phylogenetic distance increases to rabbits, the ability to isolate ESCs diminishes. To date, rabbit ESCs with *in vitro* characteristics that resemble those of murine ESCs have been reported but none make significant contributions to somatic tissues and the germline of chimeras (Tancos *et al.*, 2012).

In mice, ESC-like cells can be isolated from the epiblast of post implantation embryos. Although these ESC-like cells share morphological features and several *in vitro* characteristics with mouse ESCs, there are some important differences. For example, they grow more slowly, they do not respond to LIF, and they require fibroblast growth factor. Functionally, germline chimeras cannot be created from these ESC-like cell lines. Stem cell cultures from ungulate embryos share many of the properties of murine epiblast derived ESC-like cells. In some cases, ESC-like cultures from ungulate embryos have expressed genes such as Nanog, Sox2, or telomerase, and formed embryoid bodies *in vitro* and contributed to teratomas *in vivo*. To date, however, none have demonstrated the capacity to make either significant contributions to somatic tissues or contribute to the germline when injected into recipient embryos. The details of the *in vivo* and *in vitro* characteristics of embryo derived cell cultures from livestock are presented in excellent reviews by Blomberg and Telugu (2012) and Gandolfi *et al.* (2012).

Avian Pluripotential Cell Lines

Two pluripotential cell lines with unique attributes have been isolated from chicken embryos. One of the cell lines is referred to as an ESC because it is morphologically similar to murine ESCs (**Figure 2**) and it shares many of the gene expression profiles of its murine counterpart (van de Lavoir *et al.*, 2006a; Jean *et al.*, 2012). In spite of their morphological similarity, however, chicken ESCs contribute only to somatic tissues when returned to an embryonic environment. Chicken ESCs can be genetically modified and the genetic modifications are expressed in a tissue-specific and developmentally regulated manner (Zhu *et al.*, 2005). The contribution of ESC-derived tissues in chimeras can be altered by compromising the recipient embryo using irradiation, time, and temperature to produce chicks that appear to be completely derived from the donor ESCs (van de Lavoir *et al.*, 2006a). Unlike their murine counterparts, however, unequivocal contributions to the germline have never been reported even in the presence of extensive contributions to somatic tissues.

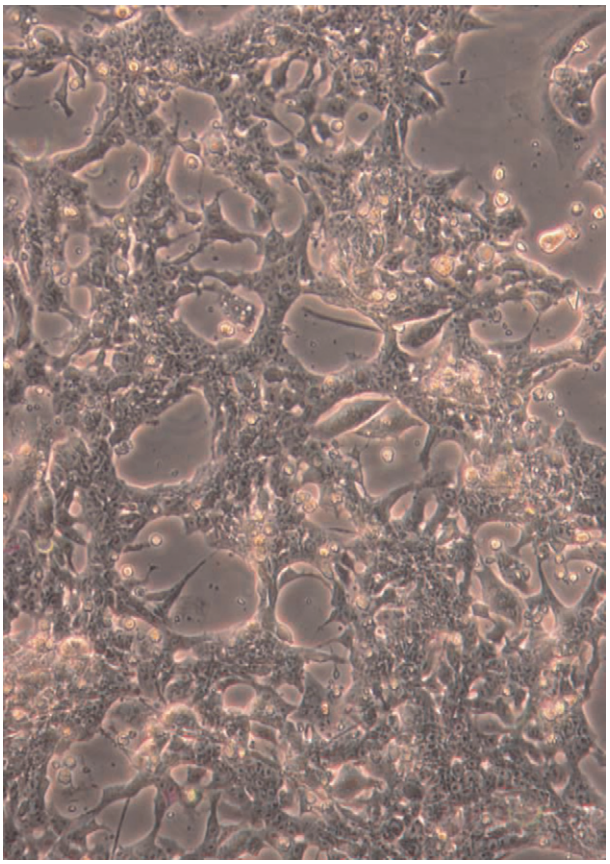

Figure 2 Chicken embryonic stem cells are characterized by their small size, large nucleus, and prominent nucleolus. Reproduced from van de Lavoir, M., *et al.*, 2006b. High-grade transgenic somatic chimeras from chicken ESCs. Mechanisms of Development 123 (1), 31–41.

The second pluripotential cell line isolated from chicken embryos is derived from the primordial germ (PG) cell lineage. In culture, these cells retain the morphology and non-adherent features of their *in vivo* counterparts (**Figure 3**). The media contains a buffalo rat liver (BRL) feeder layer and BRL conditioned media. When injected into the vasculature of Stage 13–17 (H&H) recipient embryos, avian PG cells migrate to the developing gonad and colonize the germline of G0 chimeras. Some of the G0 chimeras will transmit the PG cell-derived genotype to their G1 offspring and several lines of chickens expressing GFP have been produced using this technology (van de Lavoir *et al.*, 2006b; Macdonald *et al.*, 2010; Kim *et al.*, 2010; Macdonald *et al.*, 2012; van de Lavoir *et al.*, 2012). In addition, chickens with specific modifications in the heavy and light chain immunoglobulin genes are being produced as part of a novel discovery platform for therapeutic antibodies (see Section Relevant Websites).

Stem Cells as Vehicles for Creating Transgenic Animals

One of the compelling reasons to identify culture conditions that support the propagation of pluripotential stem cells is the introduction of genetic modifications to create 'transgenic' or

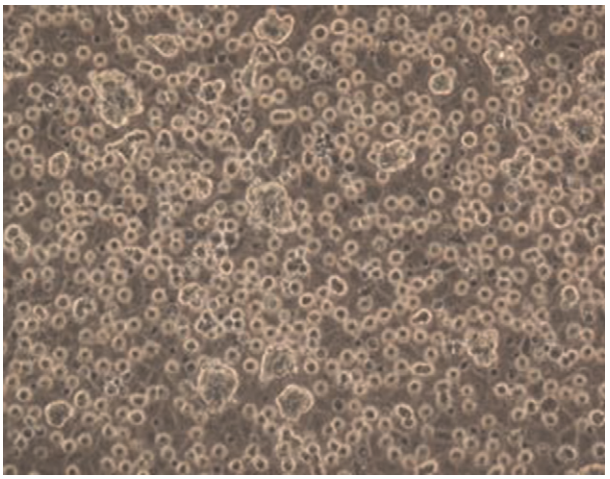

Figure 3 Chicken primordial germ cells are non-adherent, large, single cells with abundant cytoplasm. Reproduced from Song, Y., Duraisamy, S., Ali, J., *et al.*, 2014. Characteristics of long-term cultures of avian primordial germ cells and gonocytes. Biology of Reproduction 90 (1), 15, 1–8.

'genetically modified' animals. This utilitarian objective imposes parameters on the culture conditions that separate experimental protocols from robust procedures. Typically, introduction of genetic modifications into the genome occurs at a frequency between 10^{-5} and 10^{-8}. Hence, a culture must contain at least 10^5–10^8 cells to support a reasonable expectation that the desired genetic modification can be recovered. Typically, the likelihood that murine ESCs or chicken PG cells will contribute to the germline declines as their duration in culture increases. Therefore, the cells must propagate at a sufficient rate to obtain 10^5–10^8 cells in a period of several weeks. Because the genetic modifications are inserted into the genome at a low frequency, the culture used for injections into embryos is derived from a single founder cell, which must be expanded to 10^5–10^6 cells for evaluation, injection, and storage. These constraints of growth rate, efficiency of genetic modification, and a general decline in the ability of cells to contribute to the germline as the culture ages require a cell cycle that is completed within 24–36 h. When cell division occurs at longer intervals, the facilities, time, and cost of creating transgenic animals become prohibitive.

The long gestation periods of domestic mammals and consequent significant interval between injection of a putative ESC and recovery of the genotype in G1 offspring could be overcome by using ESC nuclei in SCNT. This idea receives support from studies in mice showing that the efficiency of nuclear transfer is greater when the donor nucleus is derived from an ESC (Hochedlinger and Jaenisch, 2002). Nevertheless, the overall rate of production of animals by SCNT is typically less than 3% of all reconstructed oocytes.

Induced Pluripotential stem Cells

In 2006, Takahashi and Yamanaka reported that adult mouse fibroblasts could be reprogrammed into an ESC-like state by introducing Oct4, Sox2, Klf4, and c-Myc (Takahashi and

Yamanaka, 2006). This remarkable discovery sparked an intense debate about the equivalency of ESCs and induced pluripotential stem cells (iPSC), which now appears to be resolved. In general, there is as much variation between lines of murine iPS cells and murine ESCs as there is within lines of these two cell types. Although there is considerable variation in the ability of both cell types to contribute to the germline of recipient embryos, some cell lines of each type can give rise to viable mice that are completely derived from both ESC lines and iPSC lines (Nagy *et al.*, 1993; Boland *et al.*, 2009). In principle, therefore, iPSC could be derived from all classes of livestock and used directly as ESCs or indirectly as nuclear donors for SCNT. The advent of induced pluripotential cells in mice has provided insights into the molecular events that occur as somatic cells acquire an ESC-like phenotype and these data may be applicable to reprogramming of somatic cells from livestock species (Buganim *et al.*, 2013). To date, however, none of the putative iPSC lines from livestock or poultry, which express some of the *in vitro* characteristics of murine ESC, have demonstrated significant contributions to somatic tissues or the germline.

Lineage-Specific Stem Cells

Research with stem cells in livestock and poultry has primarily focussed on pluripotent cell lines and their application to cloning and genetic engineering. In horses, however, mesenchymal stem cells derived from adipose tissue or bone marrow have been used in the treatment of tendinopathies (Muttini *et al.*, 2012). To date, this novel approach to the difficult problem of treating tendinopathies in horses has not been used in a sufficient number of clinical situations to evaluate effectiveness. As the field of stem cell biology matures, the utility of tissue-specific stem cell treatments might gain wider acceptance if they deliver both short- and long-term benefits.

Stem Cells and Genetic Engineering

Applications of stem cell technology in domestic animals are frequently associated with the introduction of modifications to the genome and this application is often used as the rationale for developing pluripotential cell lines (Etches, 2006; Petitte *et al.*, 2004; Sang, 2004; Park and Han, 2012). In chickens, the stem cell approach has provided a route to make both random (van de Lavoir *et al.*, 2006b; Macdonald *et al.*, 2010; Kim *et al.*, 2010; Macdonald *et al.*, 2012; van de Lavoir *et al.*, 2012) and site-specific (Schusser *et al.*, 2013) modifications to the chicken genome. By contrast, genetic engineering in domestic mammals has been achieved using SCNT and cloning. It is reasonable to ask, therefore, if stem cell technologies continue to be relevant to the livestock industries. From a biological perspective, an understanding of the molecular mechanisms that confer a stem cell phenotype to embryonic cells derived from early embryos would reveal fundamentally important information about pluripotentiality. Extrapolation from mouse experiments suggests that SCNT using a pluripotential stem cell as the nuclear donor would increase the proportion of embryos carrying the desired genotype and therefore a concerted effort to isolate cells with an ES phenotype is warranted. In addition, tissue-specific and lineage-specific stem cells could have important roles in veterinary medicine and could be important models as stem cell therapies are developed in human medicine.

Glossary

Bagasse Fibrous material remaining after crushing and extracting juice from sugarcane stalks.
Biomass Dry matter produced by plants.
Bolting The formation of seed stalks by sugar beet.
C3 Photosynthetic system of most plants of temperate regions.
C4 Photosynthetic system of many important tropical crop plants, including grasses, such as maize, sorghum, and sugarcane.
Evapotranspiration The loss of water from a given area by evaporation from the soil surface and by transpiration from plants.
Mega grams per ha (Mg ha^{-1}) An equivalent to metric tons per ha; when multiplied by 0.446 equals short tons (2000 pounds) per acre.
Photosynthesis The process by which green plants utilize the sun's energy to produce carbohydrate from carbon dioxide and water.
Photosynthetically active radiation The spectral range of solar radiation from 400 to 700 nm used by plants for phtotosynthesis.
Stand The number and distribution of plants after emergence from seed or vegetative cuttings.
Sucrose ($C_{12}H_{22}O_{11}$) The sugar of world commerce.
Ton 2000 lb, when multiplied by 1.102 equals 1 MT (mg).

Overview

Sucrose, the common sugar of commerce, is synthesized in most plants as a temporary storage product for photosynthetically reduced carbon, and it is the principal form of carbon transported in plants. Sucrose is typically converted into starch for long-term storage, especially in the seeds of plants, but accumulates to an exceptional degree in unmodified form in sugar beet (*Beta vulgaris* L.) and sugarcane (*Saccharum officinarum* L.). These two crops produce nearly all of the world's supply of sucrose, the 'sugar' of commerce. Small amounts of sucrose and alternative sweeteners are produced from sorghum, agave, stevia, and other sources of natural sweeteners; from high fructose syrup derived from maize grain; and increasingly from noncaloric synthetic sweeteners. Sugar production is a global, agroindustrial enterprise, with 123 countries producing sugar (43 beet, 71 cane, and 9 both, Figure 1). In 2013, approximately 20% of the world's sugar supply was derived from beets and nearly 80% from sugarcane (FAOSTAT, 2013). The most recent estimate for world sugar (sucrose) production is 160 million metric tons. Sugar consumption has been growing at roughly the same rate as world population or 2% per year. There are substantial differences in per capita sugar consumption among nations worldwide. It is highest in Europe and lowest in China and Africa. Sucrose from cane and beets is also converted into ethanol and a wide range of consumer products and feedstock chemicals, substituting for nonrenewable petroleum.

Sugarcane is a perennial tropical grass with highly efficient C4 photosynthesis, high yields, and the ability to provide harvests for several years without replanting. It is suitable for low-technology hand planting and harvest as well as amenable to automation. Production is heavily concentrated in the countries of South America and Asia (Table 1). Brazil has the largest area devoted to sugarcane production for both sugar and ethanol and dominates world sugarcane production. A crop of temperate and Mediterranean regions (Figure 1), sugar beet is a biennial crop grown as an annual. For the most part, it is intensively farmed and is one of the most efficient crop plants. Over time, production technology has come to include a long list of innovations in plant breeding, mechanization, pest management, and fertilizer practice. Sugar beet-producing regions lie north and south of the 30th parallels. It must be grown in rotation with other complimentary crops. Most sugar beet and sugarcane production is rain fed, but in Mediterranean to arid regions, irrigation is necessary.

Origin and History of Sugar Crops

Sugar Beets

Sugar beet (*B. vulgaris* spp. *vulgaris,* L.), a genus of the family Amaranthaceae (formerly Chenopodiaceae), is one of the diverse and useful group of cultivars from the same species that includes Swiss chard, fodder beet, and red beet (McGrath, 2011). The first modern sugar beets originated as selections made in the middle of the eighteenth century from fodder beets grown in then German Silesia, but food and medicinal uses of the genus are much older. A precursor is known to have been used as food as early as dynastic times in ancient Egypt. In 1747 a German chemist, Andreas Marggraf, demonstrated that the crystals formed after a crude extraction from pulverized roots were identical to sugarcane crystals (sucrose). Attempts to derive sugar from beets, and the beet sugar industry itself, originated from this work. His student Karl Achard developed processing methods for sugar extraction from beet and made the first selections of higher sugar-type beets. The blockade of shipments of cane sugar to Europe by the British during the Napoleonic wars stimulated the industrialization of sugar production from

beets, especially in France, through a more intensive search for sweeter beets, an innovative plant breeding program, and the construction of many crude factories in France and elsewhere in Europe. After the battle of Waterloo (1815) and the lifting of the British blockade, the incipient sugar beet industry in France declined for a time, but effectively a new crop had been created and the efficacy of sugar extraction from the beet had been demonstrated. The beet industry not only continued to expand in Europe, which remains the center of the industry, but also developed in other countries in the Middle East and North Africa; Central Asia and Japan; and North and South America. The first successful commercial factory in the United States was constructed by E. H. Dyer Alvarado, in California, in 1879. Soon after, sugar beet culture and factories expanded in many states.

Sugarcane

In contrast to sugar beet, sugarcane has been used as a sweetener in India and China for nearly three millennia. An early ancestor of commercial sugarcane spread from Asia into Papua New Guinea, which became a center of diversity and a major site of domestication. Selected sugarcanes spread throughout the Pacific Basin from around CE 8000, with eventual reintroduction of domesticated clonal materials to South and Southeast Asia. Domesticated clones spread throughout the Pacific islands with exploration and migration, reaching Hawaii by CE 750 (Barnes, 1974). Sugarcane was introduced to Europe from India in the fourth century CE by Alexander the Great and again from the Middle East by returning Crusaders in the Middle Ages. It came to the Americas with Columbus in CE 1493. Successful production was established in Haiti and the Dominican Republic (formerly Hispañola) in 1506, in Puerto Rico in 1515, and in Mexico by 1520 (Barnes, 1974; James, 2004).

Sugar was a luxury in European economies until extensive cultivation of sugarcane began in the Caribbean islands and Central and South America (James, 2004; Galloway, 1989). This allowed a more than hundred-fold increase in English sugar consumption between the mid-1600s and mid-1900s. Sugar use increased along with the Industrial Revolution and the broad appeal of inexpensive and rapidly prepared calories to support urban factory workers who no longer produced their own food. Per capita consumption was also fostered by the increased availability of newly introduced beverages, including coffee, cocoa, and, in England especially, tea, all typically consumed with sugar. Sugarcane provided nearly all sugar in world commerce until the commercialization of sugar beet in the nineteenth century.

Impacts of sugarcane production had substantial impacts on the global labor force. The development of a global sugar market based on sugarcane was closely associated with development of a global market in slave and later indentured labor. Sugarcane production throughout the Americas was dependent on importation of African slaves beginning in the early sixteenth century (James, 2004). By the eighteenth century a major component of international commerce was the exchange of slaves for sugar, molasses, and rum. Slavery was abolished over a prolonged period, ending in the British colonies by 1838, in United States' sugarcane-producing areas in 1863, and in Brazil by 1888. With the abolition of slavery, and advent of wage labor, production in many areas declined precipitously.

This situation was addressed in many production systems by institution of indentured contract labor, fostering immigration of large numbers of workers, especially from China and India. Some of these laborers were eventually repatriated, but most remained as settlers after their period of indentured servitude. These social and economic forces had substantial impact on the demographics of sugarcane-producing countries, contributing to large present day communities of African, Indian, and Chinese descent in many current and former sugarcane-producing countries. More recently, labor in sugarcane enterprises has been on a more conventional wage basis, or by small holders working their own or leased plots.

Production Environments

Sugar Beets

Cultivated sugar beet is a crop of temperate and Mediterranean regions predominantly and has a C_3 photosynthetic system. It is biennial and when the growing plant undergoes prolonged exposure to cold temperatures (approximately 90 days at 5–7 °C, followed by warmer temperatures and longer days), seed stalk production ('bolting') takes place. Wild beet relatives (*B. vulgaris*, spp. *maritima*) do not require vernalization to flower, only increasing day length. Sugar beet seed will germinate and emerge at low soil temperatures (4–5 °C), but emergence is much greater at temperatures greater than 10 °C. Mature plants tolerate modest freezing temperatures, but extended exposure to temperatures below approximately −4 to −5 °C results in cell disruption and death leading to rotting, requiring harvest and storage before severely freezing temperatures occur. These limits affect the length of the growing season of beets in northern latitudes with cold winters. The farthest northern production regions with sugar industries are located in Finland and Sweden in Europe. In Mediterranean locations, like California's central valley and parts of Turkey, Egypt, and Morocco, sugar beets grow year round, but overwintered crops must be harvested by late spring to prevent vernalization-induced flowering from occurring. In arid desert regions with irrigation, like California's Imperial Valley and parts of the Middle East, extremely hot temperatures increase the susceptibility of roots to pathogens like root rots and insect pressures and reduce water-use efficiency, creating other seasonal limits to efficient production. Where successful sugar beet-based industries have developed, diverse adjustments to these effective physiological limits to crop growth have been made. In addition, pest and disease management issues, like the threat of insect-vectored virus diseases, interact with the crop's agroecological requirements in locally diverse ways to set other practical limits to crop production that are regionally specific (Section Crop Management). These factors result in a large number of different cropping patterns worldwide.

Sugarcane

Sugarcane is a tropical plant with a highly efficient nicotinamide adenine dinucleotide phosphate-malic enzyme type C_4

Table 2 Top 10 countries ranked by yield of sugarcane per land area during the period 2001–12. Yields of recoverable sugar are approximately 8–12% of these fresh cane yields

Country	*Area harvested (ha)*	*Cane production (ton)*	*Cane yield (ton ha^{-1} year^{-1})*

photosynthetic pathway. This photosynthetic pathway is generally associated with adaptation to high temperature and high light environments, and to efficient use of water as well as light, while maintaining high productivity (Sage and Kubien, 2007). The optimal environment for cultivation of sugarcane was described as one having a "long warm growing season with adequate rainfall, fairly dry and cool but frost-free ripening and harvesting season, [and] freedom from tropical storms" (Mangelsdorf, 1950). However, with irrigation this ideal changes to one with an absence of clouds, and diurnal and seasonal gradients in temperature, but still free from frost or hurricanes. These requirements are met primarily in lowland subtropical areas and in the tropical highlands, and the highest yields per land area are achieved in such environments (**Table 2**), with high irradiance, irrigation, and a cool dry season to stimulate sugar accumulation, known as ripening.

A major limitation to the expansion of sugarcane as a sugar or biofuel crop is its natural limitation to the latitudes where native *Palmaceae* (palm trees) are found (**Figure 1**). This palm zone, approximately 30° N to 30° S, accommodates the limited cold tolerance of commercial sugarcane clones and avoids the occurrence of freezing night temperatures (Ming *et al.*, 2001) that absolutely limit the current production region. Visible cold damage is not generally observed above 0 °C (Irvine, 1983), when cold chlorosis may be observed as bleached stripes across the leaf lamina. In Louisiana and Florida, risk of freezing nights dictates short growing seasons of approximately 9 months, compared with 12 months in tropical and subtropical environments. A large number of producing countries experience freezing temperatures during the off-season.

Even in the mild, subtropical, marine environment of Hawaii, sugarcane exhibits a strongly bimodal growth pattern, with substantial reduction in the cool (but not cold) winters. Physiological acclimation to progressively cooling temperatures may extend this range. Even moderate chilling may be deleterious (Moore, 1987). In sugarcane fields in Hawaii, excursions below average nocturnal temperatures of only a few degrees Celsius were sufficient to depress stomatal conductance and to substantially inhibit photosynthesis for several days (Grantz, 1989). Chilling effects on mesophyll function dominated these responses, and conductance and photosynthesis were uncoupled. This was most pronounced in summer when rates were greatest and least acclimated to chilling. The effect was also observed in spring, but not in winter, although rates were lower in winter relative to their levels in spring or summer. Extreme heat may also limit production. Sugarcane trials in the low desert of California, where summer temperatures exceed 45 °C, resulted in mid-summer bleaching of leaves in some clones. At both high and low temperatures, stomatal control of water loss may be disrupted (Grantz, 2014).

Under production conditions, flowering of sugarcane is to be avoided as it reduces growth, consumes sugar, and reduces yield. Most modern commercial clones are not heavily flowering in their adapted production environments. Flowering is required for traditional breeding but is often difficult to induce. Shortening days are required, but not sufficient. Conditions with photoperiods just exceeding 12 h, moderate day and night temperatures, and reduced fertility and water supply have been considered essential (James, 1980). For example, in Hawaii, a breeding station on the windward side of the island of Oahu provided a far more favorable environment for flowering than locations at the same latitude on the leeward side.

The Sugar beet Crop

Sugar Beet Breeding and Genetics

In countries with intensive agriculture, hybrid varieties are used for production. Hybrid creation in sugar beets is complex and is made difficult by both physiological and genetic characteristics particularly associated with sugar beets (Bosemark, 2006). These have to do with the crop's biennial character, self-incompatibility, multigerm seed formation in the Beta genome, and the wide range of environments, pest, and diseases affecting the crop in diverse production regions. Creating a new hybrid is a multiyear process. Sugar beets are self-sterile, but mating between close genetic relatives is possible. Cytoplasmic male sterility is found commonly in the Beta genome (Owen, 1945) and is used for hybrid production. However, to obtain offspring from male sterile plants that are themselves male sterile, maintainer lines (called O-types) must be produced as part of the hybrid development process, adding to the complexity of hybrid creation and plant breeding in general. In 1950, Savitsky (1952) laboriously identified a few

plants that formed single embryos (monogerms) which have become the basis for the seed industry worldwide outside of Russia, where separate lines were identified. All commercial hybrid seeds are monogerm.

In both Europe and the United States, sugar beet variety improvement and seed production are carried out primarily by private companies. However, the US Department of Agriculture (USDA) developed most of the varieties grown in the first half of the twentieth century in the United States and current variety development often uses genetic lines derived from USDA research (Panella *et al.*, 2013). Both diploid ($n=9$) and triploid hybrids are available, but increasingly, diploid hybrids are being developed due to greater ease and better adaptability to rapid incorporation of new traits (Bosemark, 2006), most recently resistance to a virus disease (Beet necrotic yellow vein virus) called rhizomania (vectored by *Polymyxa betae*) that spread rapidly to all growing regions of the world in the 1980s (Wisler and Duffus, 2000). Plant biotechnology, such as marker-assisted selection, has been used to assist the development of new sugar beet hybrids (Panella *et al.*, 2013; McGrath *et al.*, 2007). In North America, herbicide-tolerant sugar beets are now grown commercially, but their adoption in other parts of the world has been delayed by regulatory restrictions.

For most of the world, sugar beet seed is produced in narrow latitudinal ranges (44°–46° N) in northern Mediterranean areas in Italy and Southern France that have appropriate day length conditions and mild winter temperatures for seed production. Similarly in the United States, sugar beet seed is produced most efficiently in the Willamette Valley of Oregon at similar latitude. In all these locations, winter temperatures are low, but the roots do not freeze, allowing seed producers to manipulate the plant's biennial habit, and day-length conditions support selection of types less likely to flower ('bolt') during the growing season.

Most countries have a variety of testing programs to ensure the use of cultivars that are productive and well adapted to local conditions. Sugar beet breeding, together with improvements in agronomic and pest management practices, has allowed continuous yield and efficiency improvements over time (especially root yield, (**Figure 2**; Panella *et al.*, 2013; Jaggard *et al.*, 2012; Zimmerman and Zeddies, 2000). In countries with less intensive agriculture or where larger numbers of small-scale producers grow beets using less than optimal technology, yields have not risen as much indicating that there is substantial room for yield increases if supporting conditions are established.

Sugar Beet Industry Organization

Worldwide, sugar beet production, sugar processing, and marketing are carefully integrated. In North America, all the companies are grower-owned cooperatives. In other regions, either privately held or state-owned companies are found. Of necessity, there is a closer and more cooperative relationship among growers and companies than is found with many other agronomic commodities, which results in careful organization of all aspects of production from area planted, scheduling of harvest of individual fields, and through sale of the final product. Commonly, contracts between sugar processors and growers contain quality incentives (see Section Sugar Beet Growth and Management; **Figure 8**).

Sugar beet root yields (**Figure 2**) and sucrose concentrations vary widely. This variance is most strongly related to the climate where they are produced, especially the length of the growing season, local soil types, and the level of agricultural development in each region. A surprisingly diverse set of production, harvest, and processing arrangements is possible. In temperate sugar beet production regions like

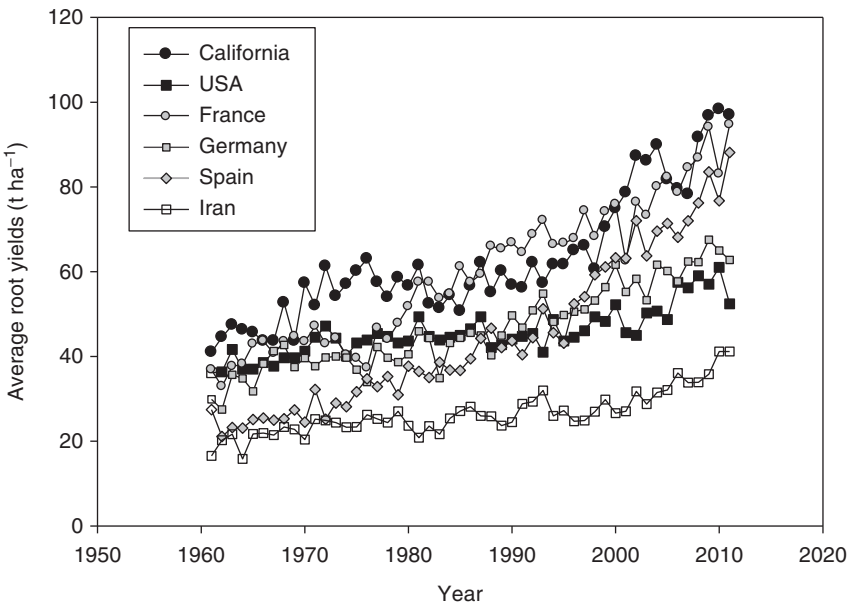

Figure 2 Root yield trends in selected sugar beet–producing countries (1961–2011). Reproduced from FAOSTAT, 2013. Food and Agriculture Organization of the United Nations. Available at: http://faostat.fao.org/default.aspx (accessed 18.02.14).

Northern Europe and most of North America, beets are planted as early as possible in spring after the danger of severe frost (usually March to April) and harvested in autumn (starting in September) for as long as soil conditions and the onset of continuously freezing weather allow. During a typical, concentrated autumn harvest campaign in Europe, factories process large amounts of raw beets to produce crystallized sugar and varying amounts of thick juice (sucrose syrup) that is stored and can be crystallized subsequently at a slower rate during the rest of the year. In the Red River Valley Region of Minnesota and North Dakota in North America, the early onset of extremely frigid temperatures shortens harvest of approximately 1 month but allows roots to be frozen in massive piles in autumn and processed until late spring, often for 200 days or more. In Mediterranean or semiarid to arid regions with milder winters, beets can grow for more than 6 months or even year round, and longer harvest campaigns are possible. In warm locations, roots must be processed shortly after harvest due to losses of sucrose from root respiration and to pathogens during storage.

Sugar Beet Growth and Management

A rapidly growing sugar beet crop is capable of high rates of sucrose accumulation. Dry matter (DM) accumulation and sugar yield are directly proportional to the amount of solar radiation absorbed by the crop (Jaggard and Qi, 2006). Other conditions being equal, the longer the growing season, the larger the yield potential. Under appropriate conditions, the plant develops quickly from seed with the seedling emerging from the soil within 5–10 days after planting under suitable soil temperature and moisture conditions. The taproot grows rapidly and may reach 30 cm or more by the time the first true leaf is developed. During the first 30 days, growth is confined primarily to its leaves and fibrous roots. After approximately 30 days both top and storage root growth proceeds rapidly, with tops reaching near maximum fresh weight in 60–90 days and canopy closure occurring at a leaf area index (LAI) of 3 (Milford, 2006). Subsequently, with favorable climate, top growth remains fairly constant but storage roots continue to grow rapidly for another 20–40 weeks (for a 10-month crop). As the crop develops, an increasing amount of DM accumulates in roots. While leaf number and area may remain relatively constant, in areas with longer growing seasons, roots consist of larger amounts of crown materials, so there is a tendency for impurities to accumulate as well. These impurities reduce sugar recovery from roots in factories (Harvey and Dutton, 1993).

As the storage root increases in size, there is a constant translocation of sucrose from the leaves to the root where it is stored primarily in concentric rings of vascular tissues derived from secondary cambium initiated early in the root's development and in root parenchyma cells that increase in number and enlarge during growth. Bell *et al.* (1996) and Milford (2006), summarizing a large number of studies, reported that DM partitioning in roots is regulated by the cells within the root and is independent of the photosynthate supply (**Figure 3**, Bell *et al.*, 1996; Milford, 2006). On a fresh weight basis, the sucrose content of the root remains relatively constant, unless suitable external factors cause the concentration to change. In temperate regions, these usually increase toward harvest but are also reported to decrease in warmer locations (**Figure 4**).

The largest average sugar beet yields come from California and France (**Figure 2**). California's Mediterranean to semiarid

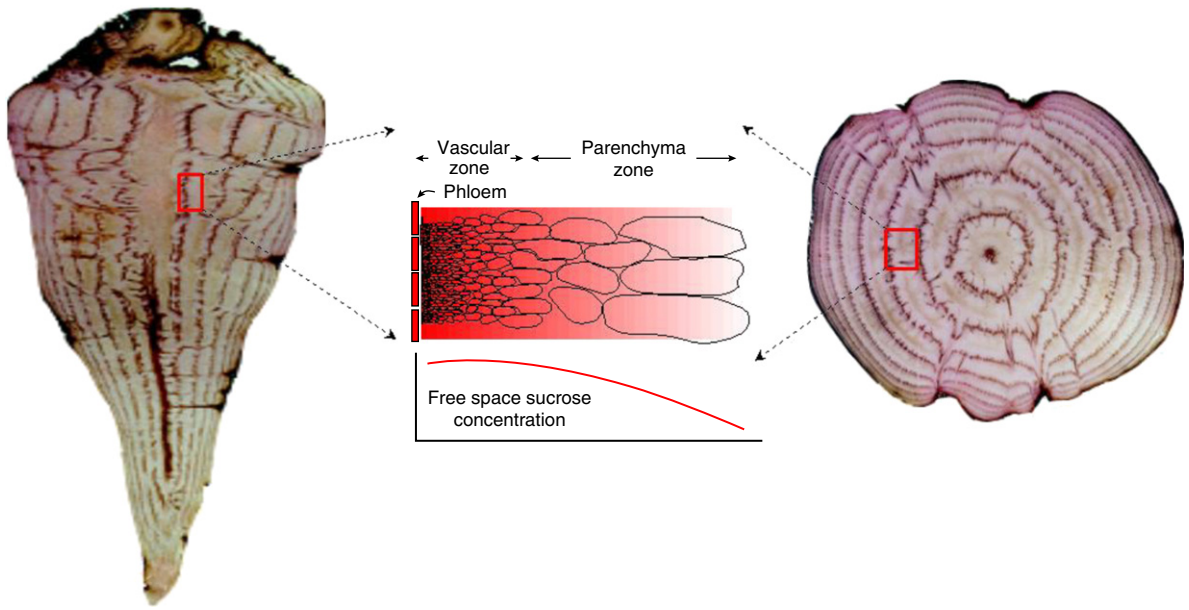

Figure 3 Longitudinal and transverse views of the secondary structure of sugar beet root. Sugar concentration is highest in cells in the vascular zones of the cambial rings visible in the root cross section on the right of the figure. Reproduced from Milford, G.F.J., 2006. Plant structure and physiology. In: Draycott, P. (Ed.), Sugar Beet. Oxford: Blackwell Publication Ltd, pp. 30–49 (Chapter 3), with permission from John Wiley and Sons.

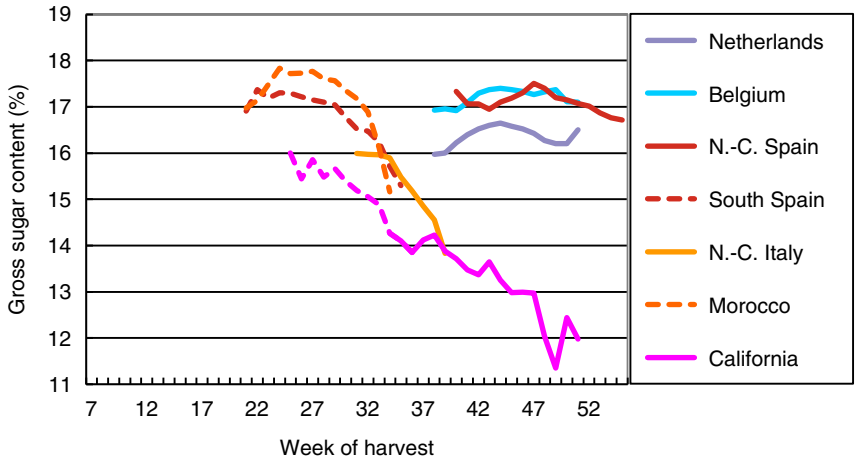

Figure 4 Root sucrose (gross sugar) concentration with time during harvest campaigns. In temperate countries or locations with cold autumn temperatures, sucrose concentrations are maintained during the harvest period, but in warmer Mediterranean locations, they tend to decline during the harvest period. Reproduced from Barbanti, L., Zavanella, M., Venturi, G., 2007. Losses in sugar content along the harvest campaign and means to contrast them. Figure 5 Dry matter accumulation (tons ha^{-1}) in a very high-yielding September-planted and July-harvested crop fertilized with 250 kg N per ha, from the Imperial Valley of California (Kaffka, 2007).

climate allows a long growing season, combined with high-quality soils and irrigation. The world's apparent commercial record yield has come from a field in the Imperial Valley in 2012 and equaled 28.0 Mg ha^{-1} of sucrose from a crop grown over a 300-day period from October to August (177 Mg ha^{-1} of roots at 15.89% sucrose; based on processor data). Average crops in this region reach 55% of the biomass and sugar yields of record crops. Over the total growing season, the record crop accumulated an estimated 147 kg total DM ha^{-1} day^{-1} (44.1 Mg total DM per 300 days) and 93.3 kg sucrose ha^{-1} day^{-1}. DM and sucrose accumulation is not uniform throughout the growing season. Initially it is relatively slow and then accelerates (Figure 5). Peak DM and sucrose accumulation rates can be double the average reported for the cropping season as a whole and most likely exceed rates of 200 kg sucrose ha^{-1} day^{-1}.

Sugar beet refining produces several products in addition to sucrose. These include molasses, dry root pulp, and monosodium glutamate, an amino acid salt used to enhance the flavor of foods. The sugar beet pulp left after sucrose extraction is used widely in the dairy and beef cattle industries as a feed supplement due to its highly digestible fiber and energy content. The tops of beets can be fed, grazed, or returned to soil as an organic matter and nutrient addition. Beet roots contain approximately 1% N, 0.1% P, and 1.1% K on a DM basis, although this varies (Cariolle and Duvall, 2006). An 80 Mg ha crop removes approximately 200 kg N, 20 kg P, and 200–250 kg K ha^{-1}, although actual amounts vary with yield and growing conditions. Because beets are efficient at accumulating photosynthate in a useful form, they are also efficient convertors of agricultural inputs, such as water and nitrogen. One of the reasons sugar beet requires relatively low use of fertilizer nitrogen is its efficiency in recovering residual soil nitrogen from previous crops or decomposed organic matter. Beets recover more of their N requirements from soils than other crops. The crop has been shown to require 25–50% less fertilizer nitrogen than maize (*Zea mays* L.) (Hills *et al.*, 1983).

Many interacting influences affect the balance between root growth and canopy growth. Sugar beets can redistribute N within the plant recovered from soils or take up additional N from soils. Redistribution buffers variations in soil N supply. As long as crops have the amount of N needed for optimum sugar yields, they are capable of sustaining fast rates of root growth and sugar production throughout the growing season without additional supply from the soil or fertilizer. A rapid increase in root sucrose content is correlated with cool night temperatures in the fall of the year coupled with a nitrogen deficiency. It has been repeatedly established that sugar beets require only modest levels of N to produce the highest sugar yields and that beets appear to recover more of their required N from soil reserves than other crops (Hills *et al.*, 1983). Ulrich and Hills (1990), working in California, established a method of plant testing to identify surplus or deficiency and suggested

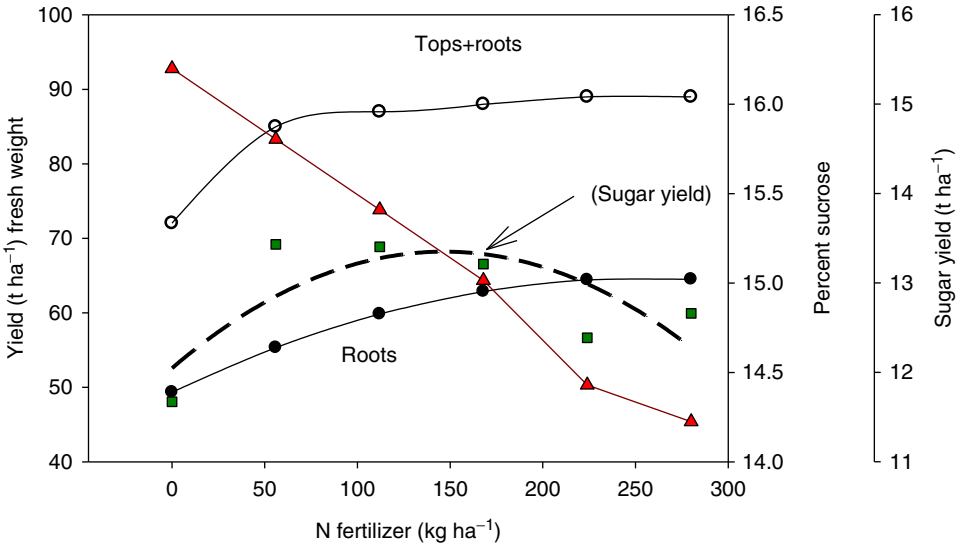

Figure 6 Root and sugar yields of a typical sugar beet crop. Reproduced from Hills, F.J., Sailsbery, R., Ulrich, A., 1982. 'Sugarbeet Fertilization,' Bulletin 1891. Oakland, CA: University of California, Division of Agriculture and Natural Resources.

that 1200 mg N per kg DM in mature leaf petioles was a reliable indicator for sufficiency of non-N limiting sugar beet growth. Generally, nitrogen fertilization is required for profitable sugar beet production. However, sugar yield is sensitive to the absolute amount and the timing of N availability, requiring sufficient amounts early for maximum vegetative growth, and also to a period of N deficiency before harvest for proper sugar accumulation in the storage roots. The highest sugar yields, a function of root yield and sucrose concentration, usually are achieved with a fertilizer rate lower than that which maximizes root yields (**Figure 6**; Hills *et al.*, 1982; Cariolle and Duvall, 2006). Excess N fertilizer results in larger total DM accumulation, but lower total gross and extractable sucrose yields, and could lead to losses of N to the environment. Milford *et al.* (1988), Armstrong and Milford (1983), and Hills *et al.* (1983) all reported that beets require lower levels of N than many other crops for maximum sugar yields and that sugar beet can serve as a nitrogen-scavenging crop to prevent possible nitrate pollution of groundwater. N fertilizer use has tended to decline with increasing yields. Milford (2006) and Milford *et al.* (1988) suggested that environmental or agronomic factors that affect the size and rate of development of the shoot influence sucrose accumulation in the root.

When N becomes deficient before harvest, leaf initiation and expansion is slowed relative to photosynthesis, and photosynthetically produced sucrose accumulates in roots as storage rather than as new vegetative growth. This is illustrated by results from California, where production occurred over a diverse set of climate conditions, allowing comparison of crops in different locations at the same time of year. Kaffka *et al.* (2001) found that very high sucrose concentrations occurred in sugar beet roots harvested in October from a high elevation growing region with a continental climate, where aridity results in very high levels of photosynthetically active radiation, but where higher elevations (1200 m) also correlated with night time temperatures at or near freezing in autumn. Naturally high organic matter soils provided large amounts of N mineralized from soil organic N. They suggested that leaf initiation and expansion (favored by excess N) was suppressed by cold temperatures at the end of the growing season to a greater degree than photosynthesis, favoring sucrose accumulation. Root storage tissues continue to develop in sugar beet as long as assimilate is available. Similarly, in California's milder central valley at the same time of year, sucrose concentrations in sugar beet roots typically declined in October under conditions with milder average temperatures, as deep-rooted crops recovered residual soil N supplies under conditions of declining water stress (**Figure 4**). Similar behavior with respect to beet sucrose concentration in autumn is widely reported from other temperate (Cariolle and Duvall, 2006) and Mediterranean regions with mild temperature conditions in late autumn that encourage additional crop growth (Barbanti *et al.*, 2007).

Improvements in plant breeding and seed technology have led to increasing levels of seed emergence and establishment, with the result that hand labor long associated with sugar beet production, especially around stand establishment, has been eliminated where modern agricultural technology is available. Over time, monogerm seed, improved weed control, improved planters, and seed treatments that reduce losses to pathogens and insect pests during the vulnerable period of crop emergence and establishment have reduced the need for large seed populations and hand thinning of seedlings. Planting to a stand and 70–80% emergence and establishment have become common in growing areas with advanced agricultural practices. Ideal plant populations are 75 000–80 000 plants per ha on 50–76 cm rows (Jaggard and Qi, 2006).

Most sugar beet production in temperate regions is based on rainfall and stored soil moisture. Variable weather at times results in water stress and yield limitations when rainfall is inadequate or poorly timed with crop demand. In arid and Mediterranean areas, careful and timely irrigation is essential for economic yields. Furrow or sprinkler irrigation is possible,

and some drip irrigation systems are being used. Irrigation water requirements in locations where irrigation supplements growing season rainfall are small (100–200 mm per year), but in climates where irrigation is necessary, they commonly range from 600 mm of water per ha per season in a cool climate where the soil is filled with plentiful winter rain to as much as 1200 mm per ha in an arid location with a long growing season like the Imperial Valley of California (Dunham, 1993; Hills *et al.*, 1990). DM accumulation and sugar yield are a linear function of transpiration, although both are more easily and commonly correlated with evapotranspiration (ET) (Dunham, 2003). Actual irrigation amounts depend on the depth of the rooted profile, soil water-holding capacity and available water at the start of irrigation, planting and harvest dates, the length of the growing season, and climate during the growing season. Diverse estimates of water-use efficiency have been measured reflecting this varying set of influences.

Water-use efficiency for both total DM yield and sugar yield tends to decrease in warmer climates with higher temperatures and light intensities, where season-long irrigation is required, compared with locations with supplemental irrigation. Empirically determined water-use efficiency values for total DM production (q_{et}) and for sugar production (s_{et}) are summarized by Dunham (2003) and modified with additional data by Langner (1996). For total DM these ranged from 0.0068 Mg cm^{-1} ha^{-1} in Great Britain for a spring-planted crop to 0.0023 Mg cm^{-1} ha^{-1} in California's arid summer for the same. For sugar yield, at the same locations, values ranged from 0.004 to 0.0013 Mg cm^{-1} ha^{-1}. Intermediate values were also reported from environments with growing conditions less mild or extreme (**Table 3**). Beets are deep rooted, with many reports of soil water depletion to 2 m and some to 3 m (Kaffka *et al.*, 1999; Hills *et al.*, 1990). When grown on soils that have been preirrigated or that have large amounts of available water in the soil profile, maximum yields can be achieved at levels less than 100% irrigation (**Figure 7**), (Morillo-Velarde and Ober, 2006; Langner, 1996). In irrigated regions, if beets can be produced during the winter period, very high levels of water-use efficiency can be achieved (**Table 3**).

Sugar beet is a halophytic species that requires Na (Draycott and Christiansen, 2003) and tolerates salinity. It is considered one of the most tolerant crops (Maas, 1990) and can be produced by using low-quality water resources, like saline tile drainage water, in part, and on salt-affected soils (Kaffka *et al.*, 2005, 1999; Moreno *et al.*, 2001). When using drainage or other wastewater, care must be taken to account for N present in the irrigation water, because that reduces sucrose yields, even if it does not affect total DM.

Controlling pests and diseases is important for profitable crop production. Sugar beet is slow to establish and is susceptible to weed competition in its early stages. Moderate weed infestation is controlled by crop rotation and a combination of chemical and mechanical methods. In the United States, herbicide-tolerant sugar beet is now being grown but is not widely used elsewhere due to regulatory restrictions. Sugar beet is susceptible to preemergence and postemergence seedling rots known collectively as damping-off diseases. Other important diseases that must be controlled in areas where they occur are as follows: curly top, a virus disease transmitted by the sugar beet leafhopper; sugar beet yellows, a virus complex consisting of one or more different aphid-transmitted viruses; powdery mildew (*Erysiphe polygoni* DC) and Cercospora leafspot (*Cercospora beticola* Sacc.), diseases caused by leaf fungi; rhizomania caused by a virus (beet necrotic yellow vein)

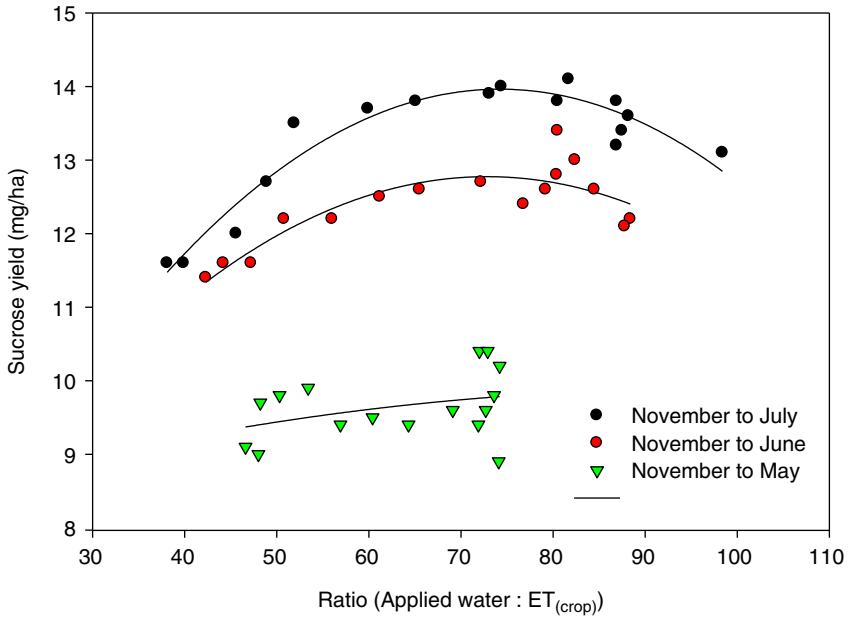

Figure 7 Sucrose yield in successive harvests from a fall-planted, summer-harvested trial in California's San Joaquin Valley, compared with the ratio of irrigation to measured crop evapotranspiration. There was little response to irrigation when the crop was harvested in May. In June and July, deficit irrigation resulted in the largest sucrose yields. Sugar beets were able to recover water from the soil profile in a way similar to their capacity to use residual soil N. Reproduced from Langner, P., 1996. Consumptive water use of fall planted sugarbeets in the San Joaquin Valley of California. MS Thesis, University of California, Davis.

transmitted by a soilborne fungus (*P. betae* Keskin); and sugar beet cyst nematode (*Heterodera schachtii* Schmidt) and root-knot nematodes (*Meloidogyne* sp.). Strategies for the control of these diseases involve development of resistant varieties, attention to time of planting, isolation of new plantings from old sugar beet fields that can serve as sources of virus inoculum in locations with year-round growing climates and practices, the selective use of fungicides, soil fumigation, and careful attention to crop rotation (Wisler and Duffus, 2000; Whitney and Duffus, 1986). Varietal resistance, including from transgenic sources, may become increasingly important (McGrath *et al.*, 2007). But currently there are limits. Foliar diseases, root rots, and insect predation are reasons why beets have not been widely grown in regions with humid, hot temperature conditions during the growing season.

Although diverse production conditions result in differing planting and harvesting practices, sugar extraction and processing is remarkably similar in most beet factories throughout the world. Because sugar factories are expensive industrial facilities, it is prudent to operate them for as many days as possible. In northern temperate growing regions, beets are harvested in early to late autumn as day length and particularly temperature decline. Severe frost damages roots and causes rotting, so freezing weather with temperatures sufficient to freeze soil marks the end of the harvest period. Consequently, factories are designed to maximize the amount of beets that can be washed, sliced into cossettes, and diffused each day. Still, many more tons of beets are needed to support a modern sugar factory than can be processed only during sometimes short harvest periods in autumn. The problem of extending beet supplies to factories is solved variably, depending on interacting local circumstances. In most of Northern Europe, some sugar beet roots are stored along field margins under cover and delivered in late autumn as factory capacity allows. In the northern tier of US states (Idaho, Montana, Wyoming, and Michigan) cold weather beginning in early autumn allows recently harvested roots to be stored outside in piles with ventilation to maintain cool but not frozen conditions. In the Red River Valley region of Minnesota and North Dakota (USA), exceptionally cold weather beginning early in autumn allows massive piles of recently harvested roots to be maintained throughout winter. Frozen beets are then processed during the winter months before temperatures warm sufficiently in the spring to thaw the piles. Processing campaigns can last 200 or more days.

In Mediterranean or warmer regions, beets cannot be stored without significant losses of sucrose to respiration, changes in sucrose to other hexose sugars that cannot be used to make commercial sugar, and losses to pathogens in storage piles. Consequently, daily harvesting and processing is normal. In many locations, this limits the length of time that a factory can operate. For example, in the Imperial Valley of California (mentioned previously), harvest begins in April following planting the previous September and October and lasts until late July or early August, when desert temperatures become too hot to maintain beets in fields without significant loss to root rots or other pests and diseases. In less extreme semiarid or Mediterranean locations, to allow factories to operate for longer periods, complementary planting and harvesting districts can be combined to allow daily harvest over a multimonth period. This occurred in California in the San Joaquin Valley, where both summer and winter temperatures allowed crops to grow year round. In that case, harvest began in April after winter rains using beets sown the previous May and continued until late October or early November, harvesting

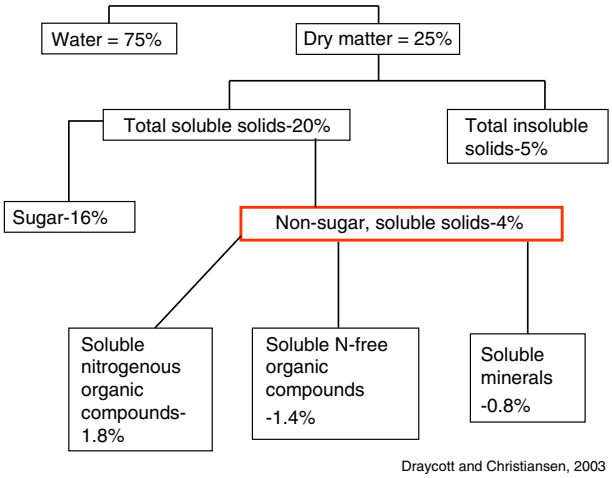

Figure 8 Composition of a typical sugar beet root at harvest. Total insoluble solids fraction is used as livestock feed (beet pulp). Adapted from Draycott, A.P., Christiansen, D.R., 2003. Nutrients for Sugar Beet Production. Cambridge: CABI Publishing, pp. 242.

beets from different regions with planting dates matched to expected harvest periods.

Creating a uniform, pure product (commercial sugar is 99.9% sucrose) from a variable feedstock is a challenging task on an industrial scale. Typical sugar beet composition is depicted in Figure 8, although all of these percentages can vary locally and seasonally. Sugar beets vary in quality as a function of many interacting factors, including agronomic practices, harvest conditions, location, and time of year. The goal of the sugar beet industry, both farmers and sugar manufacturers, is to maximize the recovery of sugar from beet roots. Sugar recovery is inhibited by the presence of large amounts of N compounds, like amino acids and by minerals like K and Na that are part of the ash content (Harvey and Dutton, 1993). Conversion of sucrose into its constituent sugars (fructose and glucose–referred to as inversion) during the diffusion process reduces commercial sugar yields and may lead to creation of other sugars that interfere with crystallization. The larger the molasses fraction, the less sucrose that can be recovered from the gross sugar stored in roots at harvest.

There is a long history in the sugar beet industry of trying to correlate crop production practices with decreased loss to molasses. Particular attention has been paid to the relationship between N fertility and fertilizer management with impurities in roots. There are a large number of regression-based formulas relating sugar recovery to amino N, Na, and K constituents in roots at harvest. These have been used to test beets at harvest and to encourage growers to produce higher quality beets through incentive payments. Formulas have varied over time and by region, with no particular formula proving to be universally applicable. The general consensus is that root quality remains elusively complex and a subject for ongoing research and empirical experimentation (Dutton and Hiuijbregts, 2006; Draycott and Christiansen, 2003).

On delivery to a factory, beets are first washed to make them free of soil and stones. Those processed immediately are then sliced into cossets and conveyed to large diffusers that dissolve sucrose and other soluble constituents from the plant. Dissolved sugar and other constituents are then passed through a series of steps that result in a purified sucrose syrup and byproducts, primarily molasses, monosodium glutamate, and proteins and amino acids (McGinnis, 1982). Residual fiber (called Marc or beet pulp) is a valuable livestock feed, not only for dairy cattle, but also for other livestock species, and even for human nutrition, and is dried for feeding purposes. Sugar beets have very little lignin, and the fiber is composed primarily of cellulose, hemicellulose, and pectin, in roughly equal amounts. Molasses may be added back to pulp if desired to further increase its energy and protein content.

The Sugarcane Crop

Sugarcane Breeding and Genetics

Sugarcane is a member of the *Saccharum* complex (Sreenivasan *et al.*, 1987). These tall, perennial, and tropical grasses include the originally domesticated sugarcane, *S. officinarum*; congeneric species, such as *Saccharum robustum*, *Saccharum sinensis*, *Saccharum barberi*, and *Saccharum spontaneum*; and various interspecific hybrids as well as related genera, such as *Erianthus*, *Ripidium*, and *Miscanthus*. *Saccharum officinarum* appears to have derived from selection and domestication of *S. robustum*. The early domesticated clones represented selection for multicolored stalks, high sap sucrose concentration, relatively low fiber, large diameter stalks, and limited tillering and flowering. The resulting 'noble canes' were those grown in household gardens in Papua New Guinea, were carried by Polynesians to the Hawaiian Islands, and formed the basis of early commercial production and crop improvement efforts.

Sugarcane improvement, as with sugar beet and other crops, is a constant requirement for the continued viability of the industry. Modern sugarcane improvement began with selection of high yielding *S. officinarum* clones in Java in the nineteenth century CE. These noble canes from the Javanese breeding collection initially dominated global commercial production. These were subsequently crossed with the wild species, *S. spontaneum*, to begin production of the modern hybrid, 'nobilized' cultivars in the early twentieth century. The noble canes were supplanted by the resulting interspecific hybrids, which exhibited improved disease resistance, broader environmental adaptation, and increased yield.

Wild *Saccharum* occurs across a surprisingly large range of rainfall and altitude (Irvine, 1983), frequently along nonsaline waterways where open vegetation allows high light penetration and where plant water deficit may be avoided. The broad adaptation is reflected in wide phenotypic diversity among *Saccharum* genotypes. For example, stalk diameter ranges from a few mm in some *S. spontaneum* genotypes to more than 10 cm in some *S. officinarum* chewing canes. Similar diversity is observed in genome structure (Hogarth, 1987; D'Hont *et al.*, 1996).

Saccharum spontaneum exhibits much greater diversity than *S. officinarum*, which does not exist outside of cultivation. *Saccharum spontaneum* is found in wild populations across Asia, North Africa, and the Middle East (Tew and Cobill, 2008). This diversity is reflected in observed variation in stress resistance (Moore, 1987) and genomic diversity (Zhang *et al.*,

2012). This diversity has contributed considerably to sugarcane improvement for the past century or more. *Saccharum spontaneum* exhibits lower stalk sucrose than the noble canes, higher fiber, thinner stalks, and sufficiently common flowering and tillering to make it a potentially invasive species. In commercial canes, sucrose accumulation and robust growth of thick stalks are derived mostly from *S. officinarum*, whereas genes for vigor, broad environmental tolerance, high fiber, and abundant tillering are derived mostly from *S. spontaneum*.

The sugarcane genome is a subject of considerable current investigation using modern genetic techniques. The *Saccharum* species are autopolyploids, with copy numbers (ploidy level) ranging from 5*x* to 16*x*. The genome of *S. officinarum* is relatively uniform among genotypes, being autooctaploid ($x=10$; $2n=8x=80$ chromosomes), with only a few possible exceptions (Zhang *et al.*, 2012). In contrast, *S. spontaneum* is more variable ($x=8$; $2n=36$–128), although approximately three-quarters of genotypes contain some multiple of 8*x* (Ming *et al.*, 2001). *Saccharum officinarum* and *S. spontaneum* appear to have diverged approximately 1.5–2.0 million years ago (Jannoo *et al.*, 2007).

The genome size differs between species, with ploidy level and with monoploid chromosome number. The monoploid genome size of *S. officinarum* is estimated to be approximately 985 Mb (million base pairs) and of *S. spontaneum* approximately 843 Mb, with much greater variation in *S. spontaneum* (Zhang *et al.*, 2012). The full polyploidy genome within the *Saccharum* complex ranges from 2–12 Gb/C (billion base pairs per diploid cell; Zhang *et al.*, 2012). Genome size is a useful surrogate for chromosome number (Zhang *et al.*, 2012).

Commercial sugarcane germplasm is largely derived from crosses of *S. officinarum* x *S. spontaneum*, with repeated backcrossing to *S. officinarum*. Current sugarcane clones contain approximately 90% *S. officinarum* and 10% *S. spontaneum* germplasm (Ming *et al.*, 2001; D'Hont *et al.*, 1996). In crosses of female *S. oficinarum* x male *S. spontaneum*, an unusual chromosomal transmission is often observed in which the diploid, somatic complement ($2n$) of the female is retained along with the haploid, gametic ($1n$) complement of the male. This so-called $2n+n$ transmission and the unpredictable pairing of the variable number of homologous chromosomes in such crosses (Ming *et al.*, 2013) result in considerable complexity in the genomes of commercial clones. Similar to other vegetatively propagated species, sugarcane is heterozygous at most loci, with no existing inbred lines that would be useful for crop improvement.

Autopolyploidy is observed in several important crop species, including sugarcane and sugar beet (Ming *et al.*, 2013; Zeven, 1979). Despite the common occurrence of this genomic replication, it presents challenges for modern genetic analysis and the search for useable markers for selection. Identification of quantitative trait loci (QTL; a genomic marker) for phenotypic traits of interest is complex, as several alleles may segregate in various combinations, and individual genes may contribute only marginally to phenotypic traits of interest.

A study of QTLs for two independent traits – sugar content and plant height – found that multiple copies of favorable alleles, in unlinked regions of the genome, had less than additive effects (Ming *et al.*, 2013). This suggests that one copy, among the multiple potential locations in the polyploid genome, may be sufficient to provide physiologically relevant protein synthesis. Additional copies may potentially be manipulated in pursuit of other desirable traits with minimal negative consequences. This may simplify development of transgenic lines, as insertion of one copy of a novel allele may be sufficient to drive improved phenotype, despite the presence of other loci with less favorable alleles. However, multiple copies of important genes may confer environmental stability (Ming *et al.*, 2013) as observed in other species. In highly selected commercial clones, favorable alleles (Lam *et al.*, 2009) have been fixed at several loci, so that identification of QTLs is more difficult than in less selected genotypes.

The recently sequenced genome of *Sorghum bicolor* (Paterson *et al.*, 2009) has proven useful as a template to understand the sugarcane genome (Ming *et al.*, 1998, 2013; Dufour *et al.*, 1997). The sugarcane monoploid size is similar to that of the haploid *Sorghum* genome (Zhang *et al.*, 2012). Sugarcane diverged from *Sorghum* less than 10 million years ago (Jannoo *et al.*, 2007; Lam *et al.*, 2009). QTLs in an *S. spontaneum* x *S. officinarum* segregating population, for both high and low sugar content (Ming *et al.*, 2013), all mapped to one of eight distinct regions of the *Sorghum* genome. Loci of interest in the larger sugarcane genome may reflect a small number of ancestral genes, simplifying manipulation during crop improvement.

Sugarcane Industry Organization

Sugarcane production took place in nearly one hundred countries (FAOSTAT, 2013) during 2001–12. Another 10 countries, mostly small producers, ceased commercial production during or before this period. Annual global sugar production from sugarcane over this period was approximately 1.7 billion tons (**Table 1**). More than 90% was produced in the top 20 producing countries (**Table 2**), concentrated in tropical and subtropical areas. Central and South America produced 53.1% of global output with an additional 36.9% from Asia and 5.3% from Africa. The remainder was distributed with 2% or less from the Caribbean region, Oceania (including Australia), North America, and Europe (0.0003%).

The largest single producer during this period was Brazil (**Table 2**), with more than 500 million tons of cane production, reflecting vigorous government investment in an integrated sugar and biofuel economy based on sugarcane. India and China produced approximately 300 million and 100 million tons, respectively. Total production is closely related to area harvested, although differences in yield per land area are observed.

Average yields were largest in Central and South America and Oceania (**Table 1**). Of the top 20 producers (**Table 2**), only three have yields at or above 100 tons ha^{-1} $year^{-1}$ – Peru (122 tons ha^{-1} $year^{-1}$), Egypt (119 tons ha^{-1} $year^{-1}$), and Colombia (100 tons ha^{-1} $year^{-1}$). Only 10 countries achieved long-term average yields of 99 tons ha^{-1} or above, mostly characterized by prolonged dry periods and long growing seasons (Waclawovsky *et al.*, 2010). Many major producers, such as Australia (82 tons ha^{-1} $year^{-1}$), the United States (78 tons ha^{-1} $year^{-1}$), and Brazil (75 tons ha^{-1} $year^{-1}$), exhibited lower average yields. Production areas, such as the

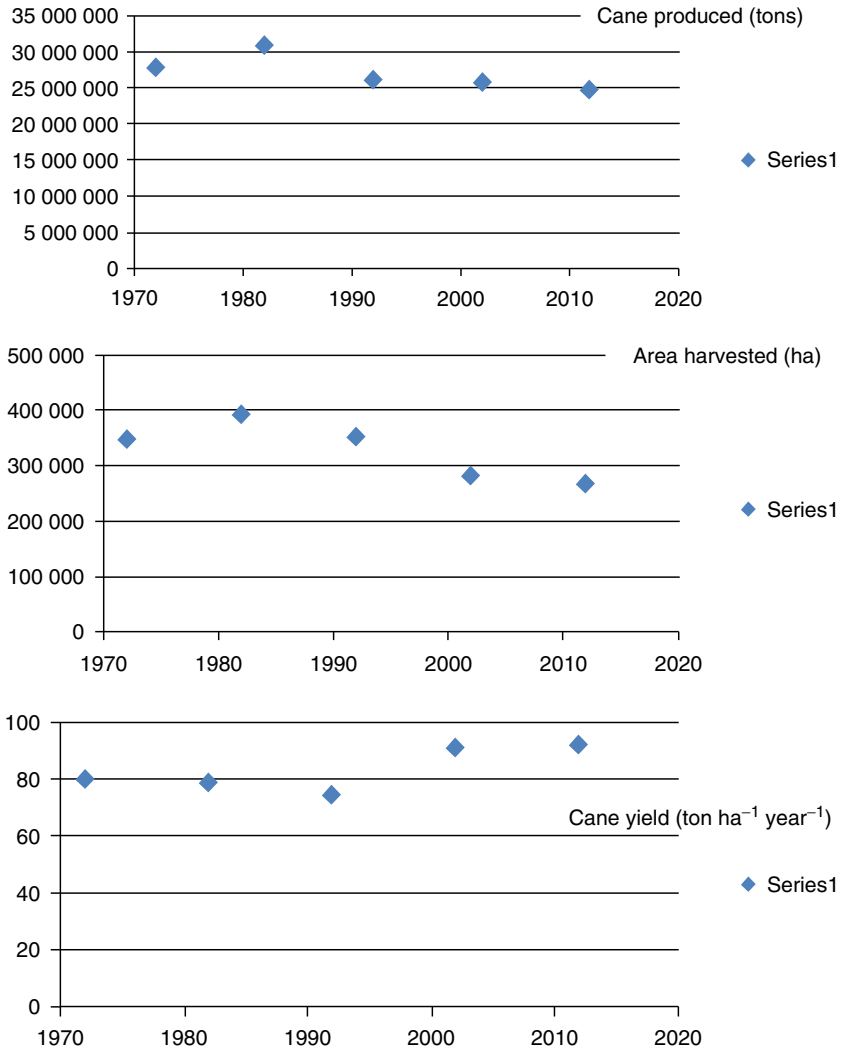

Figure 9 Fifty year trends in sugarcane production in the United States. Data obtained from the USDA National Agricultural Statistics Service (www.nass.usda.gov).

northern coastal deserts of Peru and the inland desert valleys of Southern California, arid and high irradiance environments, may provide substantial opportunities for very high yields and efficient use of limiting resources, such as land, water, and nitrogen.

Sugarcane production in the United States increased over the past 50 years (Figure 9) by 12%, although land area devoted to sugarcane increased by 28.7% (1972–2012). By 2011, the US industry had 45–47% of planted area in Florida and Louisiana, cool short season production environments, and 5.6% in southern Texas. Sugar production was 51% in Florida and only 38% in Louisiana and 5.6% in Texas. During this period the exceptionally productive Hawaiian industry declined by 87.3%. By 2011, Hawaii had 1.9% of US sugarcane plantings but 4.5% of US production. Hawaiian yields peaked at 220.0 tons ha^{-1} $year^{-1}$ shortly before the collapse of the industry on all but one of the sugar-producing islands. By 2013, only one sugar enterprise remained, on the island of Maui. These observations suggest that agronomic factors are not always decisive in determining the viability of a production system.

The sugarcane industry exists in a diverse matrix of countries, cultures, and economic systems. The organization of production reflects this diversity. In some areas, mills and production fields are owned by a single entity, commonly called a plantation system. This may represent large private enterprises or cooperative associations. A significant benefit of such organization is that improvements in both field operations (yield, production costs, sugar content) and mill operations (prevention of cane deterioration, recovery percentage, factory costs, and marketing) accrue to the benefit of both grower and refiner, and there are inherent incentives for improvement and investment in both operations. However, in much of the world, the industry is based on a large number of independent producers providing cane to mills that are operated by an unrelated entity. The result is an unavoidable conflict of interest in which incentives to increase cane quality and sugar recovery may not accrue to both parties, and

distortions of industry expansion and investment are common (Todd *et al.*, 2004).

These conflicts have been addressed through a variety of payment schemes (Todd *et al.*, 2004), each with advantages and disadvantages with respect to the economic viability of the national sugarcane industry. Payments for cane delivery may be based on the average quality of cane delivered to the mill, which removes individual grower's incentives to improve quality. They may be based on the quality of an individual grower's cane, which incentivizes the individual. This results in competition, either between the growers for a fixed share of revenues in fixed revenue-sharing systems, or between individual growers and with the mill operator for a share of total revenues in variable revenue-sharing systems. This latter option may spread risk and reward most equitably but is complex to administer and requires quality testing at multiple points in the production pathway.

An example of a management decision that may depend wholly on industry organization and payment scheme is length of the harvest and milling season. A longer season makes most efficient use of high cost-fixed equipment at the mill but inevitably reduces cane quality and sugar recovery by extending the harvest season to nonoptimal periods. Depending on grower incentives and ownership of fields and mills, this improves profitability for all participants, or only for the mill owners. In some production areas, a blended system provides individual incentives that are calculated on the basis the average quality of cane delivered during each phase of the harvest (Todd *et al.*, 2004), rather than over the entire harvest season.

Sugarcane Growth and Management

Sugarcane production methods depend on soil type, rainfall, drainage, and availability of labor and mechanized equipment. Adapted genotypes exhibit high productivity, whereas the perennial life cycle allows economically efficient production, with one or more ratoon (stubble) crops. Replanting from vegetative stalk segments is required only after several generations when yields decline due to soil compaction, disease or pest pressure, reduced plant population, or cumulative harvest damage.

Ratoon production varies with environment, cultivar, harvesting techniques, and management, ranging from no ratoon crop to four or more. From two to five appears to be a common range among current sugar production areas. Sugar yield eventually declines, necessitating a fallow period and replanting with vegetative stalk pieces. The length of the ratoon period is ultimately an economic decision, balancing replanting costs with foregone sugar yields but may be skewed by considerations of labor supply, availability of new and improved cultivars, and international sugar market conditions (Ellis and Merry, 2004).

Planting costs are substantial in sugarcane, due to its vegetative mode of reproduction. Before replanting, the seed bed is usually worked to remove the previous crop and any weeds and to optimize soil tilth. Sugarcane is planted from vegetative stalk segments. These may be long sections with only the tops removed, or they may be shorter sections, with one to three buds per section. Both types of planting material may be hand cut or delivered by mechanized harvesters from nearby fields that are dedicated to seed production. This set aside from production is a significant cost of sugarcane establishment.

Stalk segments are planted in furrows that may be subsequently filled to result in flat planting. This may provide more even water availability and is suitable for many mechanized operations. However, erosion due to water runoff and pressure from some soilborne pests may be exacerbated, and crop waterlogging in poorly drained fields may be increased. For these reasons, i.e., to channel runoff, to elevate cane above moisture and moisture-attracted pests, and to raise soil temperatures, cane is often planted in ridges separated by well-maintained furrows. Irrigation may then be provided through the furrows if available and as required. If moisture availability on the ridges is inadequate, the cane may be planted in the furrows and ridges later constructed along the plant line, although this disruptive activity may slow growth.

Row spacing reflects a balance between increased costs to produced seed cane (planting stalks) and the time required for the crop canopy to fully cover the ground for maximal interception of sunlight. Productivity is closely related to seasonal intercepted solar radiation. In practice, row separation is usually between 1 and 2 m, with narrower spacing under poorer growing conditions or where erosion is a threat (e.g., hillsides) and wider spacing where rapid growth and canopy closure is expected. In some cases, available equipment dictates row configuration.

In irrigated and highly favorable production environments, cane is harvested at approximately 12 months of age, although this may vary from 9 months in temperate climates with unsuitable winter temperatures to 24–36 months in cooler but nonchilling environments or dryland situations with water-limited growth. Sugarcane exhibits a sigmoidal growth curve, as observed in sugar beet and other crops (Figure 10). The sheer magnitude of the developing canopy has led to this exponential middle portion of the growth curve to be called the period of Grand Growth.

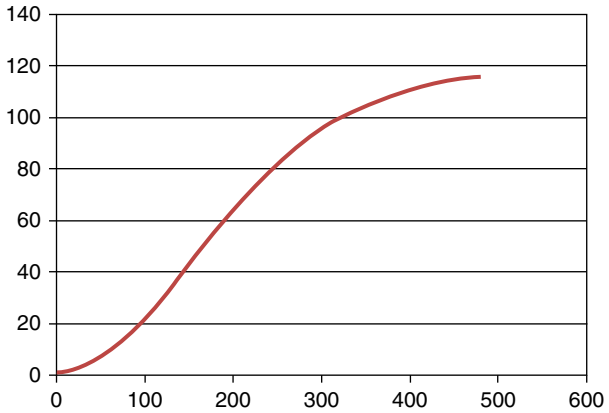

Figure 10 Biomass production in sugarcane during regrowth following harvest. This model from Simoes *et al.* (2005) describes the 4th and 5th rattoon of an early variety with vigorous regrowth in Brazil. Vertical axis is above-ground biomass (tons ha^{-1}); horizontal axis is days after cutting. The curve is generated from the equation given by Simoes *et al.* out to 480 days. $BM = 120 \times \exp(-(4.6981)) \times \exp(-(0.010098)) \times Days$.

In many production areas, sugarcane is harvested by hand, with cane knives or machetes and carried in bundles of 10–20 kg by individuals to collection points at the side of the field. Increasingly, harvest is mechanized, using machines that trim the tops and then sever the stalk near the base, leaving neatly aligned piles of intact stalks laid across the row. This type of whole-stalk or 'soldier' harvester imposes fewer cut surfaces and reduces risks of quality deterioration but requires burning in the piles and some additional logistical challenges. It is used to prepare seed cane for whole-stalk planting in some areas.

The alternative is a billet-cutting, or combine, harvester. This approach does not require burning of the trash, which is blown off during harvest by fans on the harvester. However, efficiency is improved by burning in the field. The cane is cut at the top to remove green portions, severed near the ground as above, and then chopped into convenient lengths before ejection into a receiving wagon pulled alongside. A highly mechanized system was in use throughout Hawaii until the recent decline of that industry. Fields were burned in place, then push-raked with large tracked vehicles into piles, which were loaded by infield cranes into trucks that were driven on private cane haul roads to the factory. Productivity and lodging in this system exceeded the capacity of available harvest equipment.

Burning of the cane requires that irrigation be terminated in a timely fashion and that rainfall does not occur during the critical period. The primary benefit of burning is to remove leafy field trash, both reducing the volume and weight of material to be hauled to the mill and increasing the efficiency of mill operations. Infield burning has the additional benefit of driving off or destroying pests and potentially dangerous wildlife, before entry of harvest crews. Disadvantages are the requirement for suitable weather and increasing concerns by neighboring populations regarding the hazards and nuisance of smoke inhalation.

Harvest method and the amount of soil and leafy trash carried to the mill have a large influence on sugar recovery. Growth conditions and management, particularly harvest date, may result in a wide range of juice content and soluble solids (Brix, %). High-quality sugarcane stalks typically have a Brix of approximately 18%, of which approximately 90% is sucrose. Additional factors within the mill associated with crushing and extraction, removal of impurities, and crystallization also have a large effect on sugar recovery. In general approximately 10% of fresh cane weight is recovered as sugar.

Sugarcane water requirements are substantial and highly dependent on environment and crop growth stage. Sugarcane is traditionally grown in the humid tropics, where ET is reduced by high relative humidity and where water is available for extended periods of the growing season. As cultivation has moved to higher radiation but drier environments, the risk of crop water deficit increased, and in many areas supplemental or full irrigation has been applied. Although sugarcane is considered a heavy user of water, the water requirements depend on the environment. It is most useful to consider water requirements relative to alternative crop choices. For example, in the hot, inland Imperial Valley of California, water requirements calculated from the crop coefficients provided by the UN FAO Irrigation and Drainage Paper No. 56 (Allen *et al.*, 1998) indicated that approximately 1.8 m of water was required, about the same as the existing dominant crop in the area, alfalfa (*Medicago*).

Sugarcane is sensitive to soil water depletion, with shoot extension growth declining as available soil moisture declines by less than 10%. Stomatal closure is slightly less sensitive, beginning to decline approximately 15% depletion (Nable *et al.*, 1999). In parallel experiments in large pots, the more drought tolerant, but closely related plant, *Sorghum* maintained both shoot growth and stomatal conductance until approximately 50% depletion.

Successful cultivation of sugarcane has been achieved with many types of irrigation systems, from furrow to sprinkler and drip. Under some conditions, flood irrigation of flat-planted cane may be appropriate. With the large inputs of water required by sugarcane, sufficient attention must be paid to drainage. This must provide for an unsaturated root zone to 60 cm or more (Ellis and Merry, 2004). Drainage must not lead to excessive losses of irrigation water, particularly as may occur with furrow systems in sandy fields, but must allow enough drainage through the profile to avoid buildup of salts. Available commercial sugarcane clones are not tolerant of saline conditions. Under conditions of poorly drained soils with flat gradients, it may be necessary to provide drainage aids. These may be closely spaced drainage ditches or even buried drain tile, which carry percolated soil solution to nearby ditches and away from the field.

In many production areas, runoff from sugarcane fields, with its burden of nitrates, phosphates, dissolved carbon, and pesticides, is an environmental threat to adjacent ecosystems and is highly regulated. These relatively recent pressures, as well as the long-standing imperative to control soil erosion losses, make control of water inputs and drainage an important component of management.

Fertilizer requirements depend on the environment, previous crop, and residual soil fertility. In heavier, nonpeat soils, substantial N fertilization is required for sustained yields. As in most cropping systems, nitrogen is the nutrient that is most likely to become limiting in sugarcane production (Irvine, 2004). In general, approximately 100 kg N ha^{-1} is required for the plant crop and approximately 150 kg ha^{-1} for each successive ratoon crop. Nitrogen applications must be accompanied by sufficient irrigation or rainfall to facilitate uptake. Because of the potential for losses due to deep drainage, runoff, and volatilization, application of nitrogen is typically delayed until rapid crop growth has begun and immediate uptake and utilization are most likely to occur. In production for sugar, nitrogen is applied early and the plant is allowed to deplete soil reserves. This along with dry, cool weather leads to ripening, or accumulation of sugar rather than fiber in the stalk. For bioenergy, later application of nitrogen will sustain the maximum period of biomass accumulation.

Sugarcane is understood to be less N efficient than many crop species, suggesting that alternative practices might be considered. There is recent evidence that *Saccharum* may differ from even closely related cereal crops, in preferentially utilizing ammonium rather than nitrate from the soil N pool (Robinson *et al.*, 2011). As nitrate fertilizers are labile in the environment, increased use of other, particularly more reduced, forms of N may reduce the environmental impact of sugarcane and energy cane cultivation and reduce the net greenhouse gas balance of associated biofuels.

Under some conditions, deficiencies of potassium, calcium, and phosphorous will have to be addressed, based on soil test. Other nutrients are essential but at much lower levels and are not commonly limiting, including magnesium, sulfur, iron, boron, manganese, zinc, copper, nickel, molybdenum, and chloride. Calcium is typically applied as lime before planting, usually with the intent to raise soil pH, as levels in most soils are sufficient. Addition of lime may increase the availability of phosphorous and reduce the availability of aluminum. Potassium is not often deficient, and oversupply of this element will carry over into the mill, passing through clarification to accumulate in the molasses where it impedes crystallization of sugar and reduces recovery (Irvine, 2004).

Pest management in sugarcane reflects the fact that sugarcane is typically grown in a monoculture. This accentuates the risk of epiphytotics, although sugarcane is not an extremely vulnerable crop. On a global basis, sugarcane is susceptible to a number of bacterial diseases, leading to stunted growth, occluded xylem, and foliar symptoms and a variety of fungal diseases from rusts, mildews, and smuts to rots that consume the sugar storage tissues in the stalk. Effective production requires vigilance, as unexpected diseases may appear suddenly. Although seed pieces (setts) may be treated with fungicide, the principal defense against known diseases is through genetic resistance acquired in sugarcane-breeding programs.

In some environments, insect pressure may be severe and may require treatment. Sugarcane is subject to attack by stalk-boring insects, and buried seed pieces are vulnerable to a wide variety of pests that may destroy the viable buds. Nematodes may be a problem in sandy soils. Leaf feeders are typically not a major challenge to sugarcane culture except that some, such as leafhoppers, may vector serious viral diseases. Where available, the use of biological control has often proven effective. As with pathogens, the most effective defense is genetic resistance derived in the breeding programs.

Weeds are a serious challenge in sugarcane culture because of the relatively slow canopy closure. This provides weeds a prolonged period of full sunlight and minimal competition from the developing crop. In particular, a wide variety of grasses are difficult to remove once the cane crop becomes established. If weeds can be suppressed in the early season, eventually the dense sugarcane canopy, with LAI up to seven, will provide effective suppression of most weeds. Tillage and preemergent herbicides are the most successful control strategies.

Sugarcane is grown in a large number of countries under a very wide range of conditions. Although the ancestral chewing canes were strictly tropical, with introgression of highly diverse wild relatives, sugarcane has now spread, often under irrigation, to environments characterized by cool winters and very hot summers. Sugarcane remains a dominant source of natural sweetener in global markets.

Future Prospects for Sugar Crops

Sugar Beet

With the use of sugar beets, the yield of sugar achieved in most of the principal beet-producing countries has increased substantially over the last several decades. Most of this yield progress is due to increasing root yields (**Figure 2**), although sugar content in beets has increased less or been largely stable (Jaggard *et al.*, 2012). Yield increases can be attributed to several interacting factors, including improvements in plant breeding techniques and information technology, improved seed quality and agronomic practices, and planting and harvesting machinery. Where adopted, all these practices have led to improved overall efficiency in the sugar beet industry, from crop production to factory operations (Parkin and De Bruijn, 2010). Increasing levels of atmospheric CO_2 have also contributed to increasing yields over time. Weigel and Manderschied (2012), Jaggard *et al.* (2007), Demmers-Derks *et al.* (1998), and others have correlated significant increases in root yield and total biomass under enriched CO_2 conditions when fertilization levels were sufficient to support increased crop growth. Part of the effect was attributed to warmer summer temperatures (Jaggard *et al.*, 2007). Crop nitrogen use efficiency was also improved in many industrialized production areas (**Figure 11**). Increasing levels of atmospheric CO_2 should support slowly increasing yield trends if other agronomic factors are adjusted appropriately for higher yield expectations. Donatelli *et al.* (2003) in a modeling study suggested that in regions where temperatures increase due to climate change, irrigation may be needed to sustain yield increases. Similarly, Jones *et al.* (2003) predicted significant yield increases but also increased yield variance due to more frequent occurrences of drought in parts of Europe.

Comparisons of yields and yield trends among developed and developing regions indicate that there is still substantial technical opportunity for improvement in beet crop yields in many areas of the world. For example, yields in California are two or more times greater than those in Egypt and Iran, with areas with similar climates. In recent years, there has been a significant investment made in molecular genetics and the use of transgenic traits for herbicide tolerance and pest and disease resistance has taken place. Currently, herbicide-tolerant sugar beets are grown in the United States and Canada but have not been accepted for use in other countries due to differing perceptions of risk and regulatory cultures. Nonetheless, the potential value of molecular breeding to improve crop productivity, reduce pesticide use, and increase overall efficiency is widely recognized within the industry and is expected to eventually become part of hybrid development programs (Lathouwers *et al.*, 2005).

Part of the value of molecular breeding techniques is their potential to improve environmental performance in sugar beet production systems, especially where intensive agricultural practices are carried out (McGrath *et al.*, 2007). Märländer *et al.* (2003) identified several additional new technologies for improving the environmental performance of beet production, including conservation tillage, and integrated production strategies to reduce inputs and use of pesticides and fertilizers per unit yield and off-farm emissions. Kaffka *et al.* (2005, 2001, 1999) had demonstrated the use of precision agricultural techniques and the capacity of sugar beets to use low-quality water for irrigation to improve salinity management in salt-affected areas and to recover nutrients where groundwater and surface water are affected by eutrophication. In general, there has been an improvement in the efficiency of sugar beet

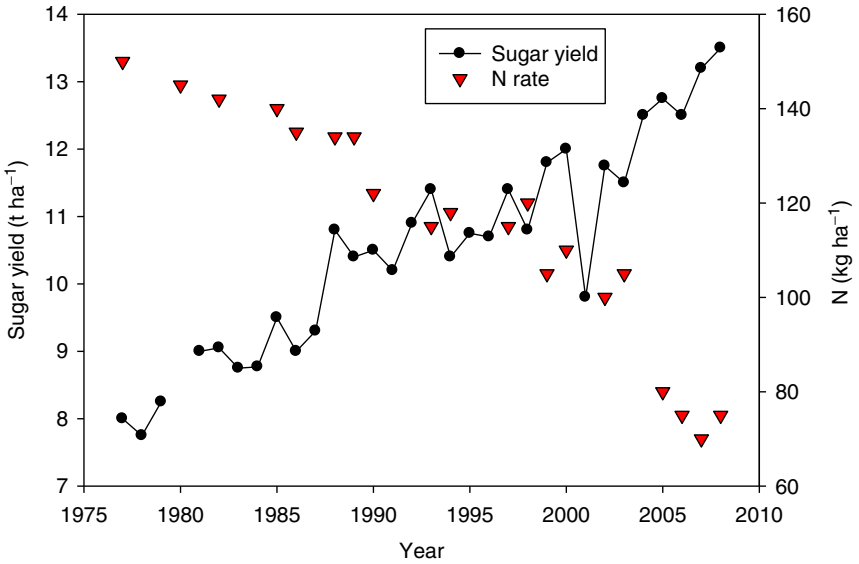

Figure 11 Yield and N fertilizer-use trends from France. Yields have increased, whereas N fertilizer use has declined. This phenomenon is common throughout the sugar beet industry in regions with developed, intensive agricultural systems. Reproduced from Cariolle, M., Duvall, R., 2006. Nutrition nitrogen. In: Draycott, P. (Ed.), Sugar Beet. Oxford: Blackwell Publication Ltd, pp. 169–184 (Chapter 8), with permission from John Wiley and Sons.

production over time. The labor invested in producing a hectare of sugar beets has declined, whereas yields have increased.

Both sugarcane and sugar beet provide a readily fermentable source of carbohydrates for conversion to ethanol, other higher alcohols, and biochemical feedstocks. The efficiency attributed to sugarcane as a biofuel source is due in part to the use of bagasse for the production of electricity needed to power the sugar or ethanol refinery. In contrast, sugar beet residues are commonly fed to livestock because they are a highly digestible feed for ruminant livestock. Because the fiber portion of beet roots is digestible and low in lignin, they can also be converted to C_6 and C_5 sugars using enzymes (Santek, *et al.*, 2010). This increases the overall sugar yield from beets available for fermentation to alcohols and makes beets a promising bioenergy feedstock (Panella and Kaffka, 2011), which compares favorably to both sugarcane and strictly cellulosic feedstocks (**Figure 12**). In Europe, some of the sugar produced at refineries in excess of sugar market requirements is converted to ethanol (Klenk and Kunz, 2008). Beet roots also digest readily when used in anaerobic digesters and are used for this purpose on a wide scale in Germany and elsewhere in Europe (Demirel and Scherer, 2008).

Sugarcane

Well-adapted sugarcane clones are considerably closer than most crop species, including those with the same photosynthetic pathway, to achieving theoretical maximal yields of approximately 6% of the energy available in sunlight (Zhu *et al.*, 2008). The maximum reported efficiency in the field is only approximately 4.3%. Maximum theoretical potential productivity of sugarcane is approximately 280 tons ha^{-1} $year^{-1}$, and with reduction for radiation striking bare ground during incomplete canopy closure, approximately 220 tons ha^{-1} $year^{-1}$ of above-ground biomass. With a harvest index of approximately 0.8 (leaving only roots, stubble, and some leafy trash in the field), potential above-ground dry biomass yield is 177 tons ha^{-1} $year^{-1}$, equivalent to 360–380 tons ha^{-1} $year^{-1}$ of fresh millable stalk material (Waclawovsky *et al.*, 2010). This is substantial relative to other potential crops.

Yields of sugarcane have increased steadily in many production areas, by approximately 1% $year^{-1}$, reaching approximately 150 tons ha^{-1} $year^{-1}$ of above-ground dry biomass under optimal experimental conditions in irrigated, high irradiance conditions in Brazil (Waclawovsky *et al.*, 2010). Record commercial yields were lower, approximately 120 tons ha^{-1} $year^{-1}$, and typical grower yields yet lower (**Table 1**), globally averaging approximately 35 tons ha^{-1} $year^{-1}$ dry biomass or 72 tons ha^{-1} $year^{-1}$ of millable cane over the first decade of the current millenium. In sugarcane, as in other crops, closing the gap between record and typical yields is an important goal for sugarcane production both for sugar and for bioenergy.

As producers around the world seek to expand production of sugarcane for sugar and bioethanol by expanding production into marginal areas, efforts will intensify to develop tolerance to drought, heat, and chilling. Efforts in Brazil to extend production to the south (higher latitudes), and in the United States to expand production northward and into the western inland valleys, have stimulated considerable efforts to enhance chilling tolerance in high-yielding clones. Genetic improvement of tolerance to heat and chilling appears feasible by selection among current germplasm, by further crossing with related wild species, particularly *S. spontaneum*, which exhibits considerable tolerance to abiotic stresses (Moore, 1987), and with the closely related genus, *Miscanthus*.

Sugarcane may represent a bridge crop for biofuel production from other sources. Current commercial clones provide sugar in high yields for direct fermentation. These clones

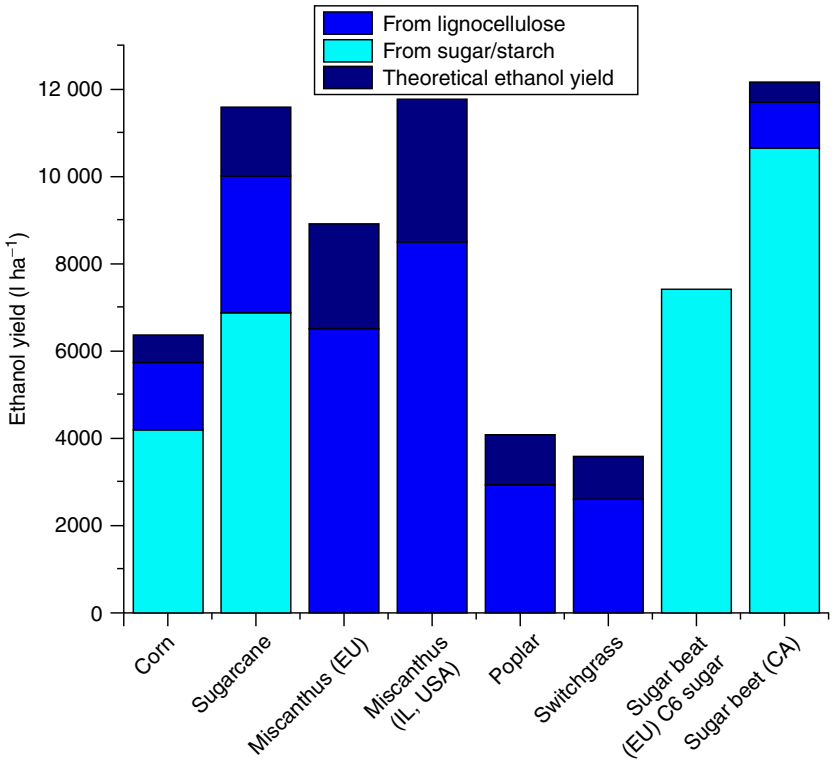

Figure 12 Potential ethanol yields from selected feedstocks. Crops like beets can be produced with high yields and efficiency using current or near-term technology. Light blue, current or simple technology, mid-blue (new or pilot-scale technology) and dark blue (no current technology available-the theoretical conversion limit). Reproduced from Kaffka, S.R., Zhang, T., Kendall, A.M., Yeo, B.-L., 2014. Advanced technology and modeling support biofuel production from beets in California. Proceedings of the 74th IIRB congress, Dresden. Available at: http://www.iirb.org/ (accessed 29.04.14).

also provide lignocellulose in bagasse and field trash (leaves) for current exploitation as a combustion fuel at the sugar mill and for future exploitation as a biofuel once required technologies mature. In many sugarcane systems, direct combustion of trash and bagasse provides much of the energy to evaporate sugarcane juice. In some areas, the material is used to cogenerate electricity, which may be produced in excess of mill requirements and sold into the local electricity grid. Current breeding programs are seeking to enhance stress tolerance and vigor, thereby reducing inputs and expanding production areas. This is done through selection and by increasing the percentage of other *Saccharum* species and related genera. Use of sugarcane to produce ethanol from sugar has the advantage of flexibility, as executed in Brazil. Here the sugar can be diverted between consumption and fermentation at short notice in response to market conditions.

Selection for high sugar has potentially created a genetic bottleneck that has narrowed the genetic resources from which high biomass and low- or high-lignin clones might be selected. This may have reduced maximum potential productivity in current commercial germplasm. This may be relieved as selection for total biomass in pursuit of efficient lignocellulosic bioenergy feedstocks is undertaken. Higher fiber clones that still contain relatively high sugar have been termed 'Type I Energy Canes' (Tew and Cobill, 2008). These were advocated some time ago by Alexander (1985). Selection within current breeding programs will most likely identify improved Type I cultivars, with somewhat higher fiber and lower sugar than conventional selections within these programs, but improved total biomass production Tew and Cobill, 2008). These may be a stop-gap solution toward maximum biofuel production.

In the long run, dedicated clones are more likely to outperform these compromise candidates in terms of biomass production, stress tolerance, and yields of lignocellulosic biofuel. These Type II clones are more likely to require separate crossing and selection programs. The emphasis will be on biomass production with stress tolerance. There appears to be considerable potential for enhanced productivity. Lignin and cellulose are coregulated at the level of gene expression (Ragauskas *et al.*, 2006) with studies in other species suggesting that repressing lignin may increase cellulose synthesis and digestibility. Further, stress tolerance has been linked to high fiber content (Ming *et al.*, 2001; Irvine, 1977), which will be more readily exploited for energy cane than it has been for sugarcane. As the lignocellulosic industry matures, selection for high- or low-lignin content may allow fine-tuning of cultivars for specific biofuel conversion processes. Improvement of tolerance to cold and heat will allow cultivation of the sugarcane feedstock in regions where the fuel markets are strongest, reducing transportation costs. In this case, market forces may reverse the decline in sugarcane and energy cane production observed in countries, such as the United States (**Figure 9**), as multiple product streams are developed.

Conclusions

A large amount of sugar from sugarcane production is diverted currently to ethanol. Brazil has demonstrated the feasibility of an integrated sugar/ethanol economy and many other countries are now developing this capacity. Ethanol from sugarcane sugar is at present one of the most efficient sources of biofuels that can be produced on a large scale. With future development of lignocellulosic processes, ethanol yields could increase by threefold, and the environmental benefits of sugarcane biofuel will be even greater (Oliverio *et al.*, 2010). However, once bagasse can be directly converted into other fuels, other cellulosic sources of biomass that produce little sugar but are inexpensive like crop residues and woody biomass will also become available. A distinct advantage of biofuel programs based on Type I or Type II energy cane clones is that the breeding, selection, management, and materials handling aspects of the production system are already well established for sugarcane. In a similar manner, this is also true for sugar beets that are used to a lesser extent as an ethanol source. These advantages of existing sugar crops will remain a factor in favoring their use compared with strictly cellulosic materials.

Some countries are more dependent on sugar production for their trade than others. Although sugar production is less important in nations that produce sugar beet, the crop has an important biological role in crop rotations and an important economic role in providing income to farmers and processing and refining jobs locally. Also, established industries representing significant capital investment have been developed to process beets into sugar. The cost of growing and processing sugar beet in the industrialized world is higher on an average than equivalent costs for sugarcane. This is due in part to differences in labor and other costs, the value of assets devoted to crop production in the industrialized and developing nations, and environmental regulations. It is unclear how trade issues affecting sugar beet production will be resolved in the future.

Glossary

Autogenous vaccines Vaccine made from microorganisms isolated from the animal it will be used on; in the United States these are killed and, by permit, are extended for use in a farm, production system, or region.
Farrow Process of parturition; location where a pig is born and stays till weaning, usually 3–4 weeks of age.
Grow–finish Phase of production that follows the nursery period where pigs reach slaughter weight; used to describe pigs from 10 to 30 weeks of age.
Histopathology; -ic The science and microscopic examination of formalin-fixed and paraffin-embedded sections of diseased tissues.
Lesion Visible (microscopic or macroscopic) deviation from normal.
National Animal Health Monitoring Service A program administered by United States Department of Agriculture-Animal and Plant Health Inspection Service.
Nursery Phase of production that begins after weaning, used to transition pigs from the farrowing house to finishing; used to describe pigs from 3 to 10 weeks of age.
OIE World Organization for Animal Health created on 25 January 1924.
Pathognomonic Characteristic of a specific disease or disorder that, when present, is sufficient to make a diagnosis.
Veterinary diagnostic laboratory Location where samples are submitted and tests are run to determine the cause of disease.

In an approach to investigating any suspected disease or disorder in swine production, a history should be gathered first. Important history to understand from caretakers includes: age of pigs affected, duration of clinical signs, morbidity rate, mortality rate, treatments administered, response to treatments, and any other important information regarding previous diagnoses or disease in the affected group of animals. This is also the time to examine any production records that have been kept on the affected group of swine as well as previous groups for comparison. Records include but are not limited to: where the animals originated from; number in the herd; age; daily mortality; number treated; name of treatment, route of delivery and dose; feed and water usage; high–low temperatures; and vaccinations received or administered. After examining the production records and obtaining a history, proceed with a visual examination of the herd. Typically, it is a biosecurity custom to observe youngest groups first; however, in cases of suspected infectious diseases, it may be best to begin with the healthiest group advancing in order of increasing severity or prevalence.

Often, a definitive diagnosis is not achieved without an extensive clinical and pathological investigation. A postmortem examination, or necropsy, of affected pigs should occur last. Any pigs recently deceased of natural causes should be examined to establish trends, with the understanding that submission of tissues from these animals may not yield valuable diagnostic results. Tissues for diagnostic evaluation should be collected from clinically affected pigs that are euthanized immediately before necropsy. Sampling of five or more pigs may be required to obtain a valuable diagnosis. When investigating signs referable to the central nervous system (CNS), it is important to preserve brain and spinal cord tissue for microscopic evaluation in cases of neurological disease; therefore, blunt force trauma and brain penetration by captive bolt are not preferred methods of euthanasia. At minimum, fresh and formalin-fixed tissue samples should include: brain, tonsil, heart, lung, lymph nodes, spleen, kidney, liver, and intestine. Additional samples that may be beneficial for diagnosis include: premortem whole blood and ethylenediaminetetraacetic acid-chelated blood (for serum chemistry and complete blood count), spinal cord, intact stifle and hock joints (remove the leg at the hip), intact eyeball with optic nerve attachment, urine, feed, and water. Consult a diagnostic lab regarding any additional samples that may be required in determining an etiologic diagnosis. The etiologic diagnosis should be based on consistent history, signs, and pathology derived from a list of differential diagnoses that are most common or most likely to occur in that herd or production system.

A treatment, control, or prevention program should be formulated simultaneously. Before using any chemical, pharmaceutical, or biologic in swine intended for food, know the domestic use guidelines, importer requirements or producer-packer agreements regarding withdrawal times, residue and tolerance limits, prescribing guidelines, and prohibited substances.

Central Nervous System Diseases and Disorders

This section will focus on a practical approach to investigating signs of neurological disease in swine summarized in Table 1. It is important to determine if clinical signs are consistent with CNS or peripheral nervous system lesions (PNS). Common CNS signs in pigs include behavioral abnormalities (most commonly stupor), ataxia, loss of righting, seizures or

seizure-like activity (paddling), nystagmus, and blindness. Musculoskeletal disorders may clinically confuse or complicate perceived PNS signs and must be differentiated from each other.

Streptococcus suis is a gram-positive cocci with 35 reported serotypes. Observational studies implicate sows as carriers and piglets are colonized as they pass through the birth canal (Amass *et al.*, 1996). Disease occurs most frequently during the suckling and postweaning period. Commingling pigs from different herds, concurrent infection with porcine reproductive and respiratory syndrome (PRRS), and other stress factors may increase the risk of developing *S. suis* meningitis (Villani, 2002; Thanawongnuwech *et al.*, 2000). Variable morbidity and mortality: mortality depends on early recognition and treatment. Clinical signs of *S. suis* meningitis include paddling, recumbency, nystagmus, and seizure. Isolation of *S. suis* from the lung, nasal secretions, or tonsil from normal pigs is clinically insignificant. In contrast, *S. suis* isolation from cerebrospinal fluid (CSF), meninges, joints, endocardium, or serosal surfaces with or without lesions is relevant (Pijoan, 1994). Few to no gross lesions may be observed during necropsy. Early recognition of clinical signs followed by injection with an antimicrobial that *S. suis* is susceptible is the most effective means of treatment. Administering an antimicrobial that *S. suis* is susceptible to in the drinking water has been proposed to control morbidity (Villani, 2002). Antimicrobial susceptibility patterns for *S. suis* isolates from regional diagnostic laboratories can be used to assist in selection of an appropriate antimicrobial while diagnostic tests are pending; ceftiofur is effective (Halbur *et al.*, 2000). Commercial and autogenous vaccines are available but due to *S. suis* serologic diversity may not be effective (Halbur *et al.*, 2000).

Haemophilus parasuis (HPS), also called Glässer's disease, causes bacterial meningitis, arthritis, and polyserositis similar to *S. suis*. Infections are not clinically or grossly distinguishable from *S. suis*. Definitive diagnosis is by bacterial isolation. However, HPS is a fastidious gram-negative rod and culture media must be supplemented with V factor for successful isolation. Owing to the difficulty in isolating HPS, Polymerase chain reaction (PCR) tests are a suitable alternative (Oliveira *et al.*, 2001). Like *S. suis*, isolation from the airways has little significance unless lesions are present (Hoefling, 1994). Antimicrobial susceptibility testing identifies ceftiofur or florfenicol that are typically effective first choice therapeutics (Oliveira, 2007b). Prevention may be achieved with medicated early weaning.

Edema disease results when a fimbrial (F18 or F4) and shiga-like toxin (StX-2e) positive strain of *Escherichia coli* successfully attaches to brush border receptors releasing toxin that damages blood vessels including those of the blood–brain barrier causing edema and encephalomalacia. Edema disease most commonly affects rapidly growing pigs, 2 weeks postweaning. Morbidity is moderate to high and mortality is high. Acute death of robust pigs, ataxia, eyelid swelling, and diarrhea are typical clinical signs (Rademacher, 2001). At necropsy, edema may be observed in the mesentery between the loops of the spiral colon and in the cardiac region of the gastric mucosa. Stomachs are usually full of feed. Bacteriologic isolation of a β-hemolytic strain of *E. coli* from affected pigs with meningoencephalitis is not sufficient for a diagnosis. Genotyping is necessary to confirm that the *E. coli* isolated was F18 or F4 and StX-2e positive and thus capable to induce such lesions. There is no effective treatment. Vaccination using an avirulent live culture of *E. coli* postweaning, thorough cleaning and disinfection between groups, and use of genetically resistance breeds that lack the fimbrial receptor are preventatives (Fairbrother and Gyles, 2006).

Pseudorabies (PRV), also known as Aujezsky's disease, is caused by a herpesvirus. PRV was eradicated from the US commercial swine herd in 2004 (USDA APHIS, 2008). Feral swine are potential reservoirs. Cattle, sheep, dogs, and cats can also be infected with PRV. High morbidity is due to large quantities of virus shed in saliva and nasal secretions for several weeks following infection. Mortality is inversely related to age approaching 100% in neonates. Clinical signs are also age dependent. Neonates may die without signs. Suckling and recently weaned pigs are those that commonly exhibit ataxia, tremors, excess salivation, and seizures. At necropsy, the brain appears congested and hemorrhagic. Necrotic foci occur in the spleen, liver, lung, lymph node, and specifically tonsils. Histopathologic lesions are characterized by nonsuppurative meningitis and intranuclear inclusion bodies. PCR, virus isolation (VI), immunohistochemistry (IHC), or fluorescent antibody can be used to confirm the diagnosis. No specific treatment is available. Vaccination and eradication are effective for control (USDA APHIS, 2008). In areas free of PRV, suspicion of the disease should be reported to state and federal agencies as required.

Congenital tremors result when hypomyelination or demyelination of the brain and spinal cord. Clinical signs are clonic muscle contractions that cause a general tremor of the entire body. Pigs are affected at birth but severity subsides with

age (Dewey, 2006). Mortality is variable and is the sequela of malnutrition because piglets are unable to nurse. There is no known treatment or prevention.

Hypoglycemia occurs when piglets fail to nurse the sow. This condition is observed within 24 h afterbirth. There is a low morbidity but high mortality. Pigs may appear disoriented, ataxic, recumbent, or dead. On necropsy, affected piglets will have empty stomachs. Assigning an employee to attend farrowing to ensure piglets nurse will reduce incidence.

Water deprivation, also referred to as salt poisoning, is an idiopathic disease resulting from a period of inadequate water intake (Carson, 2006). High morbidity with variable mortality occurs. The disease is suspected when there is a history of power outage or poor management (Thacker, 2000). Fighting over water access is the first clinical sign and occurs within hours. Dog-sitting, opisthotonous, convulsions, and fighting over water follow and develop after 24 h without water. Removal of the brain from an affected animal reveals edema and eosinophilic meningoencephalitis with perivascular cuffing and this is pathognomonic (Gudmundson and Meagher, 1961). Serum or CSF with a sodium level above160 mEq l^{-1} may also be used for supporting evidence (Osweiler and Hurd, 1974). Treatment of swine showing signs with an anti-inflammatory is variably effective. When water is restored, limit intake to short, 10–15 min intervals until all animals have had a chance to drink and fighting has ceased after which water can be provided *ad libitum*. Prevention is daily observation to ensure each animal can access water, adequate water delivery system, and equipping the facility with a generator or alternative method to deliver water during power outages.

Gastrointestinal System Diseases and Disorders

Gastrointestinal diseases and disorders can occur in all ages of swine as summarized in **Table 2**. Most digestive diseases are referable to the gastrointestinal tract and result in diarrhea and occasional vomiting. Diarrhea is the result of an intestinal dysfunction caused by malabsorption, excessive secretion, or effusion. Unfortunately, this is not an exclusive characterization of diarrhea and overlap occurs (Moeser and Blikslager, 2007). Rather, differentials for diarrhea should be referable to age at onset and site of infection.

Gastric ulcers are noninfectious and result when glandular mucosa specifically the pars esophagea is traumatized by gastric acid. Gastric ulcers have a wide variety of causes but are most commonly associated with small feed particle size (Ayles *et al.*, 1996) and interruption of feed intake whether caused by disease or poor management. It is common to see signs consistent with gastric ulceration increase following an acute PRRS or influenza outbreak. Morbidity and mortality vary with the scope of the underlying cause. Clinical signs include regurgitation, vomiting, pallor or jaundice, and acute death. An acutely dead pig with blood in its stomach is indicative of an active ulcer and is sufficient evidence for a diagnosis. In chronic cases, ulceration causes hyperplasia resulting in stricture of the pars esophagea and regurgitation. Feeding a coarse ground diet for 3 weeks significantly decreases severity (Ayles *et al.*, 1996) but is impractical in modern production facilities.

Rotavirus is a nonenveloped RNA virus with a double-layered capsid allowing it to remain stable and infective in the environment for months and intrinsically resistant to some disinfectants. Four serogroups infect swine: A, B, C, and E (the latter only reported from the United Kingdom). In addition, infections with particular serogroups vary by age: Type C mostly in suckling piglets and Type A predominately in nursery pigs (Stephenson *et al.*, 2013). Type A is the most prevalent serogroup. Severity of disease decreases with age and is self-limiting. The virus infects and destroys villous enterocytes resulting in villous atrophy. In response, crypt cells fill in the gaps but, because they are incapable of absorption, suckling piglets quickly loose body condition and have a gaunt or wasted appearance. Neither clinical signs nor gross lesions are pathognomonic although loops of small intestine appear thin-walled with moderate to large amounts of watery contents. A histopathologic report of blunted villi and crypt hyperplasia is suggestive of rotavirus infection. Infection with rotavirus can be confirmed by PCR or electron microscopy (EM). Enzyme-linked immunosorbent assay (ELISA) is also available but limited to detection of serogroup A. IHC and EM detect rotavirus and confirm its role in pathology, but both tests lack

Note: The first column provides the diseases. The remaining columns represent the respective phases of production. The frequency of the occurrence is + (occasional), ++ (common), and +++ (routine).

sensitivity. Treatment is supportive by administration of oral rehydration solutions. Acidifiers and antibiotics are sometimes administered to control secondary bacterial infections. Treatment success is variable and depends on the degree of malnourishment. Prevention among neonatal piglets is through ingestion of lactogenic virus neutralizing antibody from the sow, which is stimulated by administering feedback of Rotavirus positive piglet feces or intestines (Arruda *et al.*, 2011) or a modified-live commercial Type A vaccine no less than 3 weeks before farrowing. A modified-live commercial Type A vaccine is also available for pigs. It does not induce cross-protection for other serogroups and may be cost-prohibitive.

TGE is caused by TGEv, a coronavirus that is heat labile at temperatures above 21 °C, prone to dessication and photosensitization (Bay *et al.*, 1952). The epidemic form causes acute disease in all age groups within as little as 18 h of infection. Morbidity and mortality is high, approaching 100%, in an epizootic outbreak. The severity of disease is age dependent but all ages will develop diarrhea (Moeser and Blikslager, 2007). Postweaning infections result in high morbidity but low mortality; the most significant economic losses at this time are caused by reduced average daily gain, market weights, and overall system efficiency. Necropsy reveals that the small intestine and colon are fluid filled, the small intestinal wall is thin almost translucent, and lacteals are empty. Necrosis and atrophy are observed throughout the length of the villus. The colon and cecum are spared. The endemic form occurs when susceptible animals are introduced to the herd or after maternal antibody wanes. Prior exposure to porcine respiratory coronavirus (PRCV) may cause false-positive antibody test results. A TGEv/PRCV differential ELISA is available. In an outbreak, sows are fed tissue of diarrheic pigs to stimulate herd immunity and new introductions of animals are stopped. After the exposure and a subsequent cool-down period of 4–6 months or after clinical signs cease, sentinels can be introduced and monitored for seroconversion (Saif and Sestak, 2006). Absence of seroconversion indicates successful elimination of TGEv. Commercial vaccines are available but should be used with caution and only when elimination is not an option.

PED is caused by PEDv, a coronavirus that causes signs and histolopathologic lesions indistinguishable from TGEv. Unlike TGEv, PEDv is more environmentally resistant making elimination more difficult. The disease has been described in Europe, Asia, and, as of 2013, the United States. Prevalence of the enzootic form is approximately 50% (Chae *et al.*, 2000). Morbidity approaches 100% and mortality is 80% or more in a naïve sow herd resulting in 3–5 weeks of production losses. Clinical signs appear within 12 h; piglets develop a watery, fetid diarrhea leading to dehydration, metabolic acidosis, and death before caretakers are able to humanely euthanize them. Vomiting also occurs. The severity of disease is age dependent but all ages will develop diarrhea. Postweaning infections result in a high morbidity but low mortality; most significant economic losses at this time are caused by reduced average daily gain, market weights, and overall system efficiency. Viral shedding occurs up to 10 days postinfection. Reproductive failure and inefficiency is a sequela of an outbreak (Olanratmanee *et al.*, 2010). TGEv/PEDv differential PCR is available to confirm a presumptive diagnosis of PED. Serum can be submitted for ELISA or immunofluorescent antibody but collected no sooner than 3 weeks after diarrhea was o bserved. Immunoprophylaxis using egg antibody or hyperimmune serum and supportive care including electrolyte administration have been used for treatment. In an outbreak, sows are fed tissue and feces from diarrheic pigs to stimulate herd immunity (Olanratmanee *et al.*, 2010). Hygiene is the key to reducing environmental contamination. Preventing introduction of virus into a herd with biosecurity alone may not be sufficient because the virus has been found in aerosol up to 10 miles from a positive farm (Goede *et al.*, 2013).

Porcine coccidiosis is most often caused by *Isospora suis*. Farm hygiene, specifically farrowing rooms, and sow infestation influence the persistence of disease; however, age at infection rather than infectious dose has the greatest impact on severity (Worliczek *et al.*, 2009). The prepatent period is approximately 5 days. Morbidity is variable and mortality is low. Pasty diarrhea, unthrifty to potbellied appearance of 7–21 day old pigs, and below average wean weight is suspicious for coccidiosis. On necropsy, the small intestine often is thickened and the mucosal surface is necrotic and has an adherent pseudomembrane. Histopathologic examination of the affected portion of the intestine reveals larvae in the lamina propria. Sensitivity of fecal flotation is moderate. There is no effective treatment. Prevention is by oral administration of an anticoccidial (Maes *et al.*, 2007). Heat treatment (flaming) of flooring may reduce environmental contamination. Concrete, rubber coated and plastic flooring in the farrowing crates are difficult to clean and disinfect so removal may be the only option.

Swine dysentery (SD) is a spirochete of the genus *Brachyspira* that is an oxygen-tolerant anaerobe giving it the ability to survive for long periods of time in manure, pits, and lagoons (Schwartz *et al.*, 2012). Rodents, particularly mice, are known vectors and can serve as reservoirs. *Brachyspira hyodysenteriae* is the species known for causing SD. Other species of *Brachyspira* have been recently described in dysentery-like disease (Burrough, 2012). Incubation is 10–14 days but disease occurs in a 3–4 week cycle. Administration of tiamulin or lincomycin in the feed or water may alter the time to onset of signs after exposure. Morbidity is high and mortality is low to moderate characteristically causing disease in only the finisher and mature groups. Economic significance is mostly lost performance due to reduced daily gain and feed conversion. The specific mechanism of pathogenesis is not well understood but the spirochete does not invade the lamina propria. Clinical signs are the presence of mucohemorrhagic diarrhea containing flakes of frank blood or appearing as a generalized brick red to rust color. Lesions are mostly observed in the spiral colon where epithelial sloughing and mucosal invasion cause necrosis resulting in the formation of a pseudomembrane. The colonic walls may be thickened due to vascular congestion and mucosal hyperplasia. Bacterial culture produces strong β-hemolysis. PCR test for confirmation and speciation is recommended for any isolate with characteristic growth. Introduction of infected pigs and contaminated equipment or facilities are the source of infection. Pleuromutilins, like tiamulin, and the lincosamide, lincomycin, are effective for treatment. However, if the environment remains contaminated, clinical signs will recur. Depopulation has resulted in

successful eradication (Harms, 2011). Medicated elimination that combines thorough pulse medication with tiamulin, cleaning and disinfection, and employment of an aggressive rodent control program is also effective (Burrough and Sexton, 2013).

Escherichia coli is a gram-negative rod that infects all ages of swine but must express virulence factors to cause diarrhea. *Escherichia coli* colonize the small intestine by fimbria that binds receptors on the villous surface of enterocytes. Enterotoxigenic *E. coli* (ETEC) then produce toxin(s) that increase osmolality leading to diarrhea (Moeser and Blikslager, 2007). ETEC is subdivided by fimbria, toxin, and age of pig affected. Neonatal diarrhea (ND) is most common in pigs 0–7 days of age. The onset of postweaning diarrhea (PWD) caused by F18 is delayed, occurring 5–14 days postweaning, compared to that caused by F4 and its severity is indirectly related to wean age. Clinical signs are profuse diarrhea, rapid dehydration leading to emaciation, or death due to metabolic acidosis. Fluid filled and hyperemic sections of jejunum and ileum may be present at necropsy but few consistent gross lesions occur. Intestinal contents have a distinctly alkaline pH. Isolation of large numbers of *E. coli* and with dense layers of rod-shaped bacteria covering villi seen on histopathology in samples from pigs with diarrhea is sufficient for diagnosis of *E. coli* but not ETEC. Genotyping is necessary to determine fimbria and toxin types, which are essential to confirm diagnosis of ETEC. Treatment of affected pigs/litters/groups includes administration of antibiotics and oral rehydration solution or electrolytes to correct hyperkalemia (Kiers *et al.*, 2006). Control and prevention of ND is by passively derived lactogenic immunoglobins from vaccinated females (Kohler, 1974). Prevention of PWD include selection of genetically resistant breeds lacking K88 and F18 receptors, administration of an oral avirulent live culture to stimulate active immunity or competitively exclude field strains (Genovese *et al.*, 2000), feeding 2500 ppm zinc oxide postweaning and probiotics. Immunity and exclusion is unique to each fimbria; vaccines should include the prevalent genotype(s) causing the diarrhea.

Clostridium perfringens Type A (CpA) is a gram-positive bacillus and inefficient sporulator. Sows are regarded as the source of neonatal infection. Frequency of CpA diarrhea is on the rise in the USA. In uncomplicated cases, mortality is low whereas morbidity is high and below average weaning weights result. Cases of CpA diarrhea are associated with the expression of α and β_2 toxin. CpA is cultured from the stomach and upper third of small intestine but does not bind intestinal epithelium causing few to no histologic lesions. Because of its ubiquitous nature and prevalence among health pigs, CpA may be an opportunist and its role as a primary cause of neonatal enteritis is not definitive. Large numbers (3+ or 4+) of gram-positive bacilli cultured from feces or intestinal contents of diarrheic pigs is suggestive of CpA. Genotyping by PCR to confirm presence of *cpb2* gene in CpA isolates and rule out of other causes of ND are supportive to the diagnosis (Bueschel *et al.*, 2003). Treatment has variable success rates and is limited to administration of empirically selected antibiotics and oral rehydration solutions to affected piglets. Control of CpA enteritis is best accomplished by preventing other causes of ND. Following a thorough cleaning, sporicidal disinfectant should be applied to farrowing crates and equipment between litters and be allowed to dry before reloading. Feeding of bacitracin to sows has resulted in significant increases in weaning weights (Schultz, 2007). A commercial CpA toxoid vaccine is available (Hammer *et al.*, 2008). Autogenous whole cell vaccines are also in use. If vaccine is unavailable, feedback might be considered but should be pursued with caution (Robbins and Byers, 2013a).

CpC is a gram-positive bacillus and inefficient sporulator. Sows are regarded as the source of infection. Pathogenesis of type C is due to expression of β toxin leading to necrosis of intestinal epithelium resulting in hemorrhagic diarrhea or acute death of piglets less than 3 days of age. Gross necropsy reveals hemorrhagic and blood-filled loops of small intestine. A pseudomembrane may form on the luminal surface, and intestinal mucosa is edematous. Gross and histopathologic lesions in the presence of large numbers (3+ or 4+) of gram-positive bacilli cultured from feces or intestinal contents warrant a presumptive diagnosis. Genotyping by PCR to confirm presence of the *cpb* gene is confirmatory (Songer and Uzal, 2005). Treatment of affected piglets is unrewarding due to the rapid and debilitating course of this disease. Prevention is accomplished by vaccination of gestating females with a commercial toxoid and ensuring piglets consume sufficient colostral antibodies to result in protection.

Clostridium difficile is a gram-positive bacillus that easily sporulates making it environmentally resistant to many disinfectants. *Clostridium difficile* associated diarrhea leads to a 10–15% reduction in wean weights (Songer and Uzal, 2005). Although more than a third of piglet diarrhea involves *C. difficile*, it is the better known to cause healthcare-associated infections among humans. The pathogenesis of *C. difficile* infections is in response to the expression of toxins A and B. A watery diarrhea occurs in 1–7 day old piglets. Mesocolonic edema may be observed at necropsy. *Clostridium difficile* is difficult to culture and can be isolated from healthy piglets. Therefore, volcano lesions on histologic exam and confirmation of toxins in fecal contents by antigen ELISA are diagnostic. Treatment is ill-defined but is likely similar to that for CpA enteritis, because it is likely to be initiated based on clinical signs, which are similar. Autogenous vaccines are used to aid in prevention but efficacy is unclear.

PPE, commonly referred to as ileitis, is the general categorization of infections caused by *Lawsonia intracellularis*, an obligate intracellular bacterium. Because the bacteria cause lesions in the ileum, PPE is also referred to as ileitis. Seroprevalence in grow–finish herds can reach 100%. PPE can further be divided into four clinical forms (Kroll *et al.*, 2005). Porcine intestinal adenomatosis (PIA) is most common in 6–20 week pigs and causes little mortality. Porcine hemorrhagic enteritis (PHE) affecting pigs 28 weeks of age and older including breeding swine and can be associated with increased mortality and dark, bloody stools. Necrotic enteritis (NE) and subclinical ileitis, the most common form, occur among postweaning pigs. In all forms, transmission is by the fecal–oral route. Crypt enterocytes infected with *L. intracellularis* become hyperplastic. The altered ratio of villous and crypt enterocytes leads to malabsorption and subsequent increases in feed conversion and time to reach market weights. PIA results in variable degrees of thickened ileum that can be found at necropsy. The ileal lumen may contain a blood clot in PHE

or pseudomembrane in NE. When diarrhea ranging in color from normal (PIA, NE, and subclinical) to dark-red or black (PHE) is observed, PPE should be considered as a possible cause. Subclinical ileitis usually causes no clinical signs (Gebhart, 2007). Histopathologic lesions containing intracellular S-shaped organisms are suggestive of Lawsonia infection but IHC should be used to confirm diagnosis. PCR is helpful to detect infection and is highly specific but moderately sensitive. Cross-sectional or longitudinal serologic profiling using a widely available ELISA is the best tool for determining timing of exposure. Treatment is with effective antibiotics, such as tylosin, administered by injection or in the feed or water. Control is by administration of a commercially available modified-live oral vaccine before infection or feeding antibiotics when infection is known to occur. Vaccination should take place at least 8 weeks before seroconversion (Walter *et al.*, 2004).

Salmonellosis causing gastrointestinal disease in swine is most commonly associated with the species Typhimurium. *Salmonella* Typhimurium is commonly isolated from swine. Isolation of multidrug resistance strains of *S*. Typhimurium from swine at slaughter have garnered attention from public health and food safety professionals and it is this that make this infection significant to the pork industry (Foley *et al.*, 2008). Some European Union member states have implemented meat-juice serologic monitoring at slaughter to assess on-farm Salmonella control programs. Pathogenesis of *S*. Typhimurium is similar to *Salmonella cholerasuis* by invading enterocytes and subsequently macrophages leading to an infectious carrier state. Initial infection causes inflammation and cytokine release that result in watery, yellow diarrhea containing feed particles. Button ulcers may be visible on the mucosal surfaces of the colon and cecum on gross necropsy examination and, on histopathology, can be found to extend into the lamina propria. Bacterial isolation without using enrichment media and the presence of histopathologic lesions is consistent with a diagnosis of Salmonella enteritis. Treatment is with antibiotics administered symptomatically to diarrheic pigs. Antibiotic susceptibility of the isolate should be considered before initiating treatment. Rearing pigs on slatted floors, decreasing stocking density, and acidification of digesta are effective in reducing the prevalence of Salmonella infections in swine (Funk and Gebreyes, 2004; Boyen *et al.*, 2008). Cross-protection with *S. cholerasuis* vaccine has been reported and reduces carcass colonization (Husa *et al.*, 2009).

Whipworm infestations of swine are the result of *Trichuris suis* infection. Pigs kept on pasture, in outdoor lots, or facilities with a history of *T. suis* diagnosis are at greatest risk for disease (Pittman *et al.*, 2010a). The prepatent period is 6–7 weeks. The egg is not immediately infective, which requires 3–4 weeks in the environment. The infectious larva hatches from the egg and invades enterocytes in the small intestine and cecum. The entire life cycle of *T. suis* is completed in the intestine. Ulcerations in the mucosa and damage to capillary blood supply of intestinal epithelium lead to hemorrhage, anemia, and hypoalbuminemia. Clinical signs are depressed weight gain, increased feed conversion, bloody diarrhea, ill thrift, and death. Adult worms imbedded in the ileum, cecum, or proximal colon are sufficient for diagnosis of whipworms. Eggs are intermittently shed and thus not a reliable method of diagnosis (Pittman *et al.*, 2010a). Treatment and control are synonymous and require administration of an effective anthelmintic like fenbendazole. Prevention is by steam sanitation and drying; however, eggs are resistant to common disinfectants and remain infective for years.

Integument System Diseases and Disorders

The porcine integument or skin, like that of other domestic species, serves as a protective barrier between fragile internal tissues and harsh external hazards. Skin is comprised of layers (from external to internal): epidermis, dermis (superficial and deep), and subcutis. Blood vessels, hair follicles, sebaceous glands, and muscles are found in the dermis. Notably, the pig's skin does not contain sweat glands; therefore, modern swine facilities are outfitted with evaporative cooling systems for thermal regulation in hot climates. Skin diseases and disorders can be the result of viral or bacterial infections, parasite infestations, immunologic reactions, and idiopathic or iatrogenic causes that are summarized in **Table 3** by their various macroscopic and microscopic lesions.

Greasy pig is a skin disease of swine caused by a toxin produced by *Staphylococcus hyicus*. A break in the skin is the typical sequela. Gilt litters reportedly have a higher incidence of this disease, presumably due to deficient maternal immunity. All ages of pigs may be affected but suckling and nursery pigs are most likely to develop disease. Affected pigs develop focal crusts on the face, neck, and axillary region, and the crusts may coalesce as the disease progresses. Affected areas are greasy to touch and may appear black due to dirt adhering to it. If pigs are untreated or fail to respond to treatment, the trunk and extremities may become involved. Pyrexia and lethargy can be observed in severe cases and are followed by growth reduction. Gross appearance of affected skin is rarely confused with other skin conditions of swine. Submission of formalin-fixed skin sections that include the junction of affected and unaffected layers of epidermis and dermis for histopathologic examination is needed for a diagnosis. The pathognomonic histologic lesion is exudative epidermitis.

Table 3 Common integument diseases and disorders of pigs

	Crust	*Papule*	*Plaque*	*Pustule*	*Necrosis*	*Erythema*	*Scar*	*Scale*	*Vesicle*

Porcine dermatopathy and nephropathy syndrome (PDNS)	X	X				X			
Sarcoptic mange	X			X					

Note: The first column provides the diseases. The remaining columns represent the type of lesion that occurs.

The *S. hyicus* can be cultured from the surface of clinically normal skin sections. Treatment includes topical application of antimicrobials or disinfectants. Unaffected pigs with direct contact with affected pigs should also be treated to control spread. In cases where pigs exhibit systemic signs, administration of an injectable antimicrobial and anti-inflammatory is warranted. In the United States, no antimicrobials are labeled for the treatment, control or prevention of *S. hyicus* so all antimicrobial therapy is extra-label. Prevention should focus on facility hygiene and include a soap degreaser and disinfectant regimen to reduce contamination. In addition, scarification of the skin of breeding age females with the farm-specific *S. hyicus* strain can reduce disease incidence in suckling pigs (Murray and Rademacher, 2008).

Erysipelas or diamond skin disease is caused by a soil-borne gram-positive bacterium, *Erysipelothrix rhusiopathiae*. This zoonotic pathogen is transmitted by migratory fowl, turkeys, and pigs. Humans may become sickened when direct contact with blood from affected animals contaminates an open wound (Brooke and Riley, 1999). The finding of lesions at slaughter results in partial or complete carcass condemnation (Bender *et al.*, 2011). The disease is most common in growing, finishing, and breeding age swine. Bacterial emboli lodge in blood vessels causing vasculitis, thrombosis, and ischemia leading to lameness, abortions in gestating females, and raised, red to purple rhomboid skin lesions for which erysipelas is best known. Skin biopsies from the affected area should include epidermis and dermis, but histologic lesions are only supportive. Bacteriologic isolation or PCR identifying *E. rhusiopathiae* confirms the diagnosis. Treatment with β-lactam antibiotics including penicillin is effective. Commercial bacterins and avirulent live cultures are available for prevention (Wood, 1984) or in the face of outbreaks to prevent the chronic form.

PDNS has been associated with Porcine circovirus type 2 (PCV2) infection, but any disease process resulting in ischemia could cause result in PDNS. The condition is characterized by red to purple discoloration of skin that begins on the caudal surface of the hind limbs and the ventral surface of the abdomen resulting from ischemia. On necropsy, gross examination of the kidney cortex may be speckled with pinpoint, white foci caused by infarcted blood vessels. Pig of any age can be affected with PDNS, but it is more commonly observed during growing and finishing stages. Submission of fresh and formalin-fixed skin sections that include the junction of affected and unaffected layers of epidermis and dermis is required. There is no specific treatment or prevention; rather, diagnose the underlying cause to determine appropriate therapy (**Figure 1**).

Sarcoptic mange is the result of an allergic reaction to the saliva of ectoparasites, *Sarcoptes scabiei*. Mange may also be caused by *Demodex phylloides*. Mortality is low and morbidity is moderate. Economic losses are the result of reproductive inefficiency, growth reduction, and carcass condemnation. Infestation and subsequent clinical signs in the breeding herd, most notably an incessant scratching, develop following the purchase of infested genetic replacements. In addition, growing pigs placed in facilities that previously housed infected swine or facilities that reuse straw bedding or have solid wood partitions may also become infested. The mite is rare in modern, high-health swine operations. The burrowing mite causes red pustules and flaking skin. Individual pigs may develop signs in as few as 3 weeks but a herd may not show signs for several months. In the chronic stage, thick crusts develop at the corners of and inside the ears. Examination of a scraping from the crusts will reveal the mite (Averbeck and Stromberg, 1993). An ELISA test is used to determine prior exposure and determine success of eradication programs. Treatment can be applied topically using an antiparasitic, such as amitraz, to temporarily alleviate clinical signs. Control and eradication programs utilize feeding or injection of ivermectins (Mohr, 2001).

Musculoskeletal System Diseases and Disorders

The musculoskeletal system is comprised of tendons, ligaments, muscles, and bones. Disorders and disease of this system are typically characterized by lameness. Lameness is any deviation in normal locomotion including favoring a limb or failure to bear weight on the limb. Neurologic conditions, which also cause changes in locomotion, may be ruled out by postmortem examination of articular surfaces and diagnostic testing. Investigation of musculoskeletal diseases and disorders should always start with the claws that are easily traumatized causing pain resulting in lameness. Flooring and genetics also influence the incidence of lameness. Common musculoskeletal diseases and disorders of swine can be divided into osteopathies and myopathies and summarized in **Table 4**.

Mycoplasma hyosynoviae colonizes upper airways and tonsils resulting in a carrier state. Transmission is vertical from sow to pigs and lateral between pigs (Ross and Spear, 1973). *M. hyosynoviae* is most often diagnosed during the grow–finish phase. Morbidity is variable but mortality is low. Clinical signs are a stiff gait and difficulty in standing, most often the stifle or elbow and less frequently the hock, hip, and shoulder. Signs often occur 2–3 weeks after a stressful event; lesions begin to resolve 7 weeks postinfection. The affected joint contains yellow or blood-tinged effusion with moderate

Splayleg	+++			

Note: The first column provides the diseases. The remaining columns represent the respective phases of production. The frequency of the occurrence is + (occasional), ++ (common), and +++ (routine).

villous proliferation but is not always observed despite lameness and does not necessarily correlate with presence of histopathologic lesions. Aseptic collection of synovial fluid by needle aspiration or sterile swab or submission of the affected joint intact is recommended for diagnosis. PCR is the most sensitive test; culture requires special media and lacks sensitivity (Gomes Neto *et al.*, 2012). Histopathologic examination of formalin-fixed synovium reveals nonsuppurative fibrinous polyarthritis and lymphoplasmacytic perivascular synovitis. ELISA is also available. Lincomycin has historically been an effective therapeutic choice (Burch and Godwin, 1984). Treatment should be initiated when lameness is first observed; however, spontaneous resolution is common. No commercial vaccines are available.

Mycoplasma hyorhinis is a ubiquitous bacterium that is an early colonizer of upper airways. Transmission is vertical from sow to pigs and then between pigs postweaning (Rovira, 2009). Infection can progress to polyarthritis, polyserositis, and otitis in the pre- or postweaning phases; arthritis develops postweaning. Clinical signs include lameness, arthritis, and fever that develop 3–10 days after septicemia occurs and persists for 10–14 days (Gomes Neto *et al.*, 2012). Disease may become chronic resulting in ill thrift, reduced growth, and death. Articular surfaces may be eroded. In cases of lameness, synovial fluid and formalin-fixed synovium can be submitted. Alternatively, the entire affected leg can be submitted; disarticulate above the infected joint keeping the affected joint intact. Submission of fibrin or fibrin covered tissue(s) should be included for PCR testing to differentiate *M. hyorhinis* from other bacteria that form fibrin on serosal surfaces like HPS and *S. suis* (Rovira, 2009). Histopathology reveals fibrinosuppurative inflammation in affected tissues. Treatment is empirical.

Erysipelas is the result of a chronic *E. rhusiopathiae* infection causing arthritis and endocarditis that follows the initial septicemia. Lameness and joint swelling is mostly noticeable in hock and carpal joints. Lameness may also occur in stifle and elbow but swelling cannot be appreciated. Synovial fluid appears serosanguinous and can be submitted for testing by bacterial culture or PCR. Alternatively, the entire affected leg can be removed to prevent contamination; disarticulate the leg above the infected joint. Histopathologic examination of formalin-fixed synovium reveals a proliferative synovitis. Other lesions that occur are nonsuppurative fibrinous polyarthritis and erosion of cartilage that can progress to pannus and ankylosis. Treatment with β-lactamase antibiotics including penicillin is effective. An anti-inflammatory is added to a treatment program for pain management. Commercial bacterins or avirulent live cultures are available for control and prevention.

OC is the result of a delay in ossification of articular cartilage, and represents the most common lesion among culled sows. Morbidity is most often reported in adult and breeding age pigs (Dewey *et al.*, 1993). Mortality is variable and is the result of humane euthanasia because the animal becomes nonambulatory. OC causes lameness, pain, and joint swelling. A noninfectious lameness most often affects the distal part of the humerus or femur. Lesions are typically bilateral and symmetrical. Diagnosis is made by ruling out other causes of lameness.

Ricketts occurs as a result of phosphorus deficiency, vitamin D deficiency, or secondary to iron toxicity but is not caused by dietary calcium deficiency. The condition should be suspected when there is an increase in nonambulatory pigs and broken bones during the finishing stage particularly at and immediately before marketing. Occasionally, joint swelling in the nursery stage is observed. Rachitic rosary (enlargement of costochondral junctions) and soft bones are observed on necropsy. If rickets are present, a bone ash analysis of the second rib will be below normal. Feed analysis can identify low levels of vitamin D or phosphorus. Low levels of vitamin D or phosphorous serum chemistry also will occur (Madson *et al.*, 2012). Supplementation of vitamin D is the only reported treatment and response that may be considered diagnostic. Prevention includes proper diet formulation for the stage of production.

MHD is a noninfectious disease of muscle caused by deficiency of vitamin E or selenium. It can occur if pigs are fed grain grown in selenium deficient soils (Dewey, 2006). Clinical signs are limited to acute death of large, robust pigs. On necropsy, the heart muscle has a mottled appearance. Feed analysis, response to vitamin E supplementation, and ruling out other causes support diagnosis of vitamin E/selenium deficiencies like MHD (Hooser, 1996). Supplementation with selenium is impractical in the United States because of environmental regulations, and overzealous supplementation may cause toxicosis.

Splayleg is a noninfectious, congenital condition resulting from delayed myofibril development with no known cause. Splayleg has low morbidity and mortality as long as it is identified and corrected before it leads to starvation or being crushed by the sow. Treatment includes the use of nonslip

flooring in farrowing crates and application of harness or tape that holds the rear legs under the pig until it is strong enough to walk on its own.

Reproductive System Diseases and Disorders

Reproductive failure occurs when insemination fails to result in pregnancy or pregnancy fails to produce viable pigs due to infectious and noninfectious causes summarized in **Table 5**. Reproductive failure should be considered when a low conception or farrowing rate, irregular returns to estrus, abortions, stillbirths, or mummies persist at an abnormal rate. Infertility occurs when fewer than four embryos are present at the time of maternal recognition of pregnancy resulting in a regular return to estrus and reduced conception rate for that breeding group. Irregular returns to estrus result from embryonic death or early term abortion after implantation but before calcification of the fetuses. Embryonic death of some or all of the embryos will result in low total born or irregular return to estrus, respectively. Early term abortion also will reduce farrowing rates. Mummies and stillborns can occur any time after calcification of the fetuses. The normal rates for mummies and stillborns are <0.5 and <1 pig per litter, respectively. Late-term abortions are classified as those occurring after 70 days of gestation. Total abortion rate should remain $<2\%$ of a breeding group. These are general guidelines; thus, familiarity with the herd's normal reproductive performance is the most sensitive means to identify a reproductive problem.

PRRS is, at this time, known only to occur among swine. The estimated cost of PRRS to the US pork industry is US$664 million annually (Holtkamp *et al.*, 2013). PRRS usually results when susceptible swine are infected with either the Leylystad or North American strains of PRRS virus (PRRSv), a member of the Arteriviridae family. Viremia lasts up to 42 days, but shedding of infectious virus can last much longer (Murtaugh and Genzow, 2011). PRRSv is most commonly transmitted by introduction of infected swine or contaminated fomites, use of contaminated semen, and aerosol. The pathogenesis of the reproductive form is believed to be arteritis of fetal umbilical cords during gestation (Lager and Halbur, 1996). Swine may show no signs when reinfected with a homologous strain. Conversely, infection with a heterologous strain will reproduce lesions and disease but is usually less severe than that of naïve swine (Murtaugh and Genzow, 2011). Clinical signs of PRRS in a breeding herd start with an epidemic of abortions followed by an increase in low viable piglets, stillbirths, and mummies. Abortions result due to fetal death or pyrexia of the gestating female. Sows and gilts may be anorexic, pyrexic, or lethargic. Periparturient females may become agalactic. In severe outbreaks of PRRS, sow mortality also increases. In utero infection of feti can result in persistently infected piglets (Rossow, 1998). Prewean mortality commonly increases and may remain above the herd average for weeks. Diagnosis can be made by submitting lung, spleen, and lymph node from fetuses or low viable piglets. Whole fetuses can also be submitted but should be refrigerated to prevent autolysis. Lesions are not pathognomonic so confirmatory testing such as PCR, IHC, or VI should be conducted. Tissues and thoracic fluid from stillbirths, aborted, or mummified feti can be submitted but may result in false negatives. Serum collected from aborted sows or low viable piglets and tested for PRRSv by PCR is another option for diagnosis. PRRSv ELISA indicates previous exposure but is not useful in a previously exposed herd. Treatment of PRRS is supportive. Anti-inflammatories to reduce fever and antibiotics for control and treatment of secondary bacterial pneumonia may be necessary. The most common methods for control include depopulation–repopulation and herd closure and rollover, also called load-close-homogenize, using commercial vaccine or herd-specific live virus exposure (Corzo *et al.*, 2010). Periods of closure vary based on facility capacity but a minimum of 180 days is recommended. Commercial modified-live and killed vaccines are available but do not prevent infection and should be used in accordance with label and domestic guidelines.

PPV is sometimes described by the acronym SMEDI (stillborns, mummies, embryonic death, and infertility). PPV is an enzootic infection of swine breeding herds in the United States. The virus is ubiquitous and is transmitted through ingestion of infected feces, afterbirth, or fetal tissue. The disease most commonly affects gilts and younger parity sows (Christianson, 1992). The pathogenesis is through damage to

Note: The first column provides the diseases. The remaining columns represent the clinical signs. The frequency of the occurrence is + (occasional), ++ (common), and +++ (routine).

the placental epithelium resulting in fetal death. Clinical signs of PPV range from low total born, mummies of various sizes, irregular returns to estrus, and females diagnosed pregnant but fail to farrow. Diagnosis is based on vaccination history, clinical signs, and PCR testing of mummified fetuses. PPV ELISA may provide diagnostic value if acute and convalescent serum samples are used. There is no effective treatment for PPV; however, commercial killed vaccines are available and very effective. Exposure of unbred females to tissue or cull sows from a seropositive herd has been used for immunization when vaccine is unavailable.

Leptospirosis is caused by infection by spirochete bacteria. *Leptospira* species may be zoonotic (*Leptospira canicola*, *L. icterohemorrhagiae*), swine-adapted (*L. pomona* and *L. bratislava*), or incidentally infect swine (*L. grippotyphosa* and *L. hardjo*). Infection has been associated with exposure of swine to contaminated soil or untreated surface water, and exposure to urine from infected vectors, such as rodents. Infected swine can become carriers resulting in chronic disease. The pathogenesis is due to bacteremia resulting in transplacental infection followed by fetal death. Clinical signs include pyrexia, low conception rate, abortion, stillbirths, and low viability pigs resulting in increased prewean mortality. Diagnosis is made using dark field microscopy or IHC performed on tissues, particularly kidney, of aborted feti or stillbirths. Paired or matched serology for hemagglutination inhibition (HI) testing may be useful if suspected. Treatment with antibiotics, such as chlortetracycline, may be pursued (Henry *et al.*, 1993). Commercial killed bacterins are available to aid in prevention and should be given at least semiannually to breeding stock (Christianson, 1992) but may not be available in all countries. For example, federal regulations prohibit the use of these bacterins in France and The Netherlands (**Figure 2**).

PCV2 is a ubiquitous virus in swine facilities. Pigs become infected with PCV2 through ingestion (oral nasal contact). In addition, breeding females can become infected via insemination with contaminated semen (Madson *et al.*, 2009a). Gilts and low parity sows are affected most often, whereas boars show no clinical signs. PCV2-associated reproductive failure may occur in conjunction with PPV. Infection results in variable lengths of viremia. PCV2-reproductive failure is due to transplacental infection of fetuses. Clinical signs depend on the stage of gestation when the infection occurs. Embryonic death, early term abortions, stillbirths, mummies, low total born, or low viable pigs can result from infection. Mummies may vary in size, like PPV, and measuring crown to rump length is useful to determine the time when that fetus was infected. PCV2-reproductive failure is diagnosed by the presence of viral antigen confirmed by IHC or deoxyribonucleic acid confirmed by PCR along with the presence of lesions in fetal tissue notably myocardial mineralization. PCR testing of fetal thoracic fluid is sufficient to diagnose in utero infection of piglets (Madson and Opriessnig, 2011). Commerical killed baculovirus vectored vaccines are available and effective for prevention of disease but not infection or viremia (Madson *et al.*, 2009b).

Figure 2 Stillbirths, fetus, pig. Fully developed piglet born dead. On necropsy, lungs are deflated and fail to float in water. Presumably caused by Leptospirosis sp. Infection; breeding herd was unvaccinated. Courtesy Dr. Rebecca Robbins.

PRV or Aujezsky's disease virus was eradicated from the US commercial swine herd in 2004; a comprehensive review is available (USDA APHIS, 2008). PRV is a member of the Herpesviridae family and, like other herpesviruses, infection can result in a carrier state or latency within nervous tissue with the potential for recrudescence. The pathogenesis of PRV results from viremia, and then replication and necrosis of epithelial tissue including the placenta (Christianson, 1992). The period of viremia gives PRV time to cross the placenta and cause fetal death. Clinical signs following acute infection include embryonic death, abortion, mummies, and stillborns. Necrotic foci can be found in fetal spleen, liver, lung, and lymph node. Histopathology is not definitive; IHC is required to confirm presence of antigen. Diagnosis may also be made through serology; a commercial ELISA test is available and can differentiate between exposure to the gene-deleted vaccine and wild-type virus used extensively in the US eradication. Commercial PRV vaccines are available but only should be used in accordance with federal guidelines.

Brucellosis is a zoonotic infection caused by the bacteria, *Brucella suis* biovars 1 and 3. *Brucella suis* is transmitted through direct contact with susceptible swine, ingestion of infected tissue, or fluids including milk and contaminated semen. Pathogenesis of *B. suis* is initiated when the mucosal epithelium is penetrated, thereby resulting in bacteremia that commonly persists for 5 weeks and results in placentitis among other lesions. Clinical signs of infection in gilts and sows include abortion with or without vaginal discharge, whereas boars have reduced libido and fertility. Bacteriologic isolation of *B. suis* from vaginal discharge or tissue confirms diagnosis. Serology reflects prior exposure (or vaccination) to *B. suis* but not for diagnosis of acute disease. The US commercial swine herd is Brucellosis free.

Swine erysipelas (SE) is a zoonotic, gram-positive bacterium, which is ubiquitous among swine. *Erysipelothrix rhusiopathiae* is the sole causative species. Carrier swine shed the bacteria in saliva, nasal discharge, and feces. Infection may result from direct contact with carriers, exposure to infected facilities or soil (Wood, 1984). A bacteremia lasting several days precedes lesions. Reproductive failure is most often due to abortion but infertility and low total born following high fevers or endometritis at the time of breeding is also possible.

Clinical signs including rhomboid skin lesions, high fevers, lethargy, inappetence, withdrawal, and response to treatment with penicillin of affected sows and gilts are suggestive of acute and subacute SE. Serology is available; availability is by veterinary diagnostic laboratory (VDL) and value is limited when vaccine is in use. Bacterial culture and histopathologic examination of fetal tissue is unrewarding for diagnosis of SE but is helpful to rule out other causes of abortion. In chronic SE, culture of *E. rhusiopathiae* from vulvar discharges was successful (Gertenbach and Bilkei, 2002). Treatment involves injections of antibiotics and anti-inflammatories. Commercial vaccines are available and effective.

CO poisoning induces hypoxia resulting in an increased number of stillborns (Hooser, 1996). Concentrations of >250 ppm are toxic. Malfunctioning heating units or poorly ventilated farrowing rooms are the cause. Diagnosis is done by ruling out infectious causes of stillbirths. Fetal blood or thoracic fluid can also be measured for CO concentrations.

Zearalenone is a luteotropic mycotoxin produced by *Fusarium rosea*. It binds estrogen receptors resulting in irregular returns to estrus, signs of estrus in prepubertal gilts, and reduced litter size (Hooser, 1996). Diagnosis is by detection of elevated levels in feed samples. However, definitive diagnosis is rarely possible because the contaminated feed has long been consumed by the time reproductive failure occurs.

AAS and seasonal infertility is a noninfectious cause of reproductive failure. The declining photoperiod and temperature fluctuations during the fall months result in declining progesterone levels. High-ambient temperature experienced during lactation and the postweaning period are suspected but not confirmed as a cause. Diagnosis is done by ruling out infectious causes and careful assessment of management, facilities, and reproduction records (Rueff, 2000). Modern facilities that utilize gestation crates and evaporative cooling systems may improve but not prevent infertility during the fall months (Leman, 1992).

Respiratory System Diseases and Disorders

The respiratory system can be simply divided into upper and lower portions. The upper portion includes the nasal cavity and sinuses, throat, trachea, and bronchi for air conduction. The lower portion is the lung comprised of bronchioles and alveoli responsible for air exchange. The respiratory system is commonly involved in numerous infectious diseases of swine summarized in Table 6. The most notable infectious agents are the viral pathogens, PRRS and PCV2, which cause primary pathologic lesions to both the respiratory and the immune system. This damage to the immune system often leads to respiratory or systemic disease incited by secondary infectious agents. Such mixed respiratory infections can occur at any age, and, when they occur in growing and finishing pigs, are termed porcine respiratory disease complex (PRDC). Multifactorial respiratory disease can obscure histopathologic lesions complicating the diagnostic process.

APP is a host-adapted, fastidious, and gram-negative encapsulated rod that is transmitted vertically from sow to piglet. Morbidity and mortality are strain-specific; virulence varies with expression of ApxI and ApxII toxins. Inhalation of strains of APP expressing Apx toxins results in lung lesions within 24–36 h. The disease is economically significant because mortality occurs during the later part of the finishing phase, usually just before slaughter. Clinical signs of fever, lethargy, dyspnea, and acute death are common. Pigs found dead may have a frothy, blood-tinged discharge from the nose and mouth. Focal hemorrhage occurs in the diaphragmatic lung lobe, which is firm, and its appearance is likened to that of a bull's eye. Fibrinous, necrotizing bronchopneumonia containing streaming leukocytes is a key histopathologic feature. Bacterial culture is difficult and requires nicotinamide adenine dinucleotide (NAD)-supplemented media so diagnosis is traditionally made on finding characteristic postmortem and histopathologic lesions. A PCR test is also available. In an outbreak, the entire population should receive antimicrobial therapy parentally. Unlike many other gram-negative bacteria, APP is sensitive to a variety of antimicrobials; at Iowa State University VDL >90% of isolates were sensitive to ceftiofur, enrofloxacin, florfenicol, tiamulin, tilmicosin, and tulathromycin. Prevention is aimed at eliminating carrier swine through depopulation or by pulse medication (Marsteller and Fenwick, 1999).

Actinobacillus suis causes a hemorrhagic, necrotizing pneumonia during nursery and grow–finish phases. *Actinobacillus suis* infection has similar clinical signs and pathologic appearance to APP. Affected pigs are frequently observed in a dog-sitting position with elbows abducted. Unlike APP, lung lesions are random in their distribution and petechial

Table 6 Common respiratory diseases and disorders of pigs

	Preweaning	*Postweaning nursery*	*Postweaning grow–finish*	*Adult*
Actinobacillus pleuropneumoniae (APP)			+++	
Actinobacillus suis	+	+++	+++	
Atrophic rhinitis (AR)			+++	
Ascaris suum			+++	
HPS	+	+++	+++	
Mycoplasma hyopneumoniae (MH)		+	+++	+
Porcine circovirus associated disease (PCVAD)		+++ (PMWS)	+++	
PRRS (respiratory form)	+	+++	+++	++
Salmonella cholerasuis		+	+++	
Swine influenza (SIV)	+	++	+++	++

Note: The first column provides the diseases. The remaining columns represent the respective phases of production. The frequency of the occurrence is + (occasional), ++ (common), and +++ (routine).

hemorrhages may be seen in other organs due to the septicemia that follows *A. suis* infection (Yaeger, 1995). A PCR test is available to help differentiate disease from APP and HPS (Oliveira, 2007a). Like APP, outbreaks should be treated by parental delivery of an antimicrobial; however, treatment of only those individual pigs with clinical signs is usually sufficient. Autogenous vaccines can be used for control but response is variable because most pigs are already seropositive at the time of vaccination.

Ascaris suum, the swine roundworm, is the most common parasitic infection of swine. The reduced growth performance and liver condemnations are responsible for economic losses (Stewart and Hoyt, 2006). The prepatent period is 40–53 days. Adult roundworms are present in the manure but it is the migration of larvae through the lungs, occurring 8–10 days after ingestion of an infective egg that causes respiratory signs. A persistent cough and dyspnea result due to verminous pneumonia. The liver develops whitish spots, called 'milk spots' that are the cause of condemnations but resolve within 25 days (Stewart and Hoyt, 2006). The presence of eosinophils is suggestive of a parasite infestation. Treatment and control is accomplished using anthelmintics: dichlorvos, fenbendazole, levamisole eliminate adults and larvae; piperazine kills only adults. Proper cleaning and disinfection particularly removing fecal material between groups reduces potential for exposure but it is virtually impossible to get rid of *A. suum* once a premise is infested (Pittman *et al.*, 2010b). It is necessary to prevent access to contaminated soil.

AR is described in two forms: progressive (PAR) and nonprogressive (NPAR). PAR is caused by toxigenic strains of *Pasteurella multocida*, whereas NPAR is the result of toxigenic strains of *Bordetella bronchiseptica*. In both forms, the bacteria attach to cilia in the nasal passages and the cytotoxin production causes hypoplasia of nasal turbinates. Clinical signs include sneezing, deviated snouts, and, in cases of PAR, bloody nasal discharge occurring in a large number of grow–finish pigs. Mortality is low but the reduced growth that results due to AR makes it economically important. Beacause the cytotoxins are responsible for AR, isolation of either bacterium from nasal passages is not sufficient for diagnosis. In addition, *B. bronchiseptica* and *P. multocida* colonize the lung leading to bronchopneumonia causing cough and dyspnea in pigs postweaning, often part of PRDC (Hansen *et al.*, 2010). Therefore, examination of nasal turbinates at slaughter is the recommended method for diagnosis of AR (Gatlin *et al.*, 1996). Transmission is vertical; therefore, prefarrow vaccination of sows can protect piglets up to 16 weeks of age. If vaccination does not prevent AR, depopulation of the herd may be necessary.

HPS is also called Glässer's disease. There are 15 serovars identified and prefer to colonize the nose (MacInnes *et al.*, 2007). HPS may not actually result in pneumonia but does cause signs of respiratory disease including nasal discharge and dyspnea. In addition, fever, lethargy, and acute death are observed. On necropsy, one or all of the pleural, pericardial, epicardial, and peritoneal serosal surfaces become covered in fibrin. Effusion commonly occurs. Histopathologic lesions are described as fibrinopurulent. Definitive diagnosis is by bacterial isolation on culture media supplemented with V factor. Owing to the difficulty in isolating HPS, PCR testing is now available (Oliveira *et al.*, 2001). Isolation from the airways in the absence of lesions has little significance (Hoefling, 1994). Ceftiofur, enrofloxacin, or tulathromycin delivered parenterally to affected animals are effective therapeutic drugs. Use of water-soluble antimicrobials is for control. Maternal immunity, medicated early weaning, and controlling infections with PRRS, PCV2, and influenza postpone or prevent disease onset (Rapp-Gabrielson *et al.*, 2006). Commercial and autogenous vaccines are available but may experience limited efficacy due to serologic diversity; controlled exposure to low dose, live virulent culture is another option (Oliveira *et al.*, 2004) (**Figure 3**).

MH is known to infect pigs in production systems worldwide causing reduced growth performance and mortality. The disease is classified as enzootic pneumonia or a component of PRDC. Both manifestations of MH cause paralysis of the mucociliary escalator resulting in a severe cough and dyspnea known as thumping. Vertical and lateral transmission can occur; but, owing to its slow rate of transmission between pigs, the disease primarily occurs in grow–finish pigs (Meyns *et al.*, 2004). In addition, time of colonization with MH and disease severity are directly related (Fano *et al.*, 2007). On necropsy, well-demarcated (red to purple lobular consolidation occurs in the apical) diaphragmatic, and accessory lung lobes is visible. Histopathologic lesions characteristic of MH is bronchopneumonia with lymphocytic perivascular, peribronchial, and peribronchiolar cuffing. Because MH is difficult to isolate, PCR is the most sensitive method of detection. ELISA is available and is helpful in establishing herd status but must be interpreted in the context of vaccination as tests do not distinguish between antibodies produced subsequent to vaccination or field infection. Treatment of affected pigs with parental antimicrobials like enrofloxacin, tulathromycin, or lincomycin or administration of water-soluble lincomycin, tiamulin, or tetracyclines to affected groups is effective in outbreaks. Control can be achieved through pulse-medication in feed of chlortetracycline (Thacker *et al.*, 2006) beginning

Figure 3 Epicarditis, heart, nursery pig. Fibrin gives surface a granular appearance, caused by HPS infection. Note the enlarged (draining) mediastinal lymph nodes located cranial to the base of the heart and the excess thoracic fluid (reddish-brown) indicative of septicemia. Courtesy Dr. Glen Almond.

1 week before the historical onset of disease (Maes *et al.*, 2008). Commercial vaccines are whole cell bacterins marketed to reduce lesions but do not prevent disease or slow transmission rate. Simultaneous infection with PRRSv reduces efficacy of MH vaccination (Thacker *et al.*, 2000; Thacker, 2000). Eradication from the herd is preventative but practically difficult to accomplish.

PCVAD is any disease process where PCV2 infection results in lesions and includes PMWS (Ellis *et al.*, 1998) and PDNS. Infection with PCV2 is widespread. Morbidity and mortality is variable, often dependent on the occurrence of secondary infections and their virulence. Survivors of PCVAD remain stunted, owing to the economic significance of this collection of diseases. Clinical signs include wasting, dyspnea, depression, ill thrift, and diarrhea. Lungs are wet, heavy, and fail to collapse; pulmonary edema and lymphadenopathy also can be found at necropsy. Histopathology results include presence of interstitial pneumonia, lymphoid depletion, enteritis, nephritis, and dermatitis. For a diagnosis of PCVAD the following must occur: PCV2 antigen within characteristic lesions and lymph nodes are depleted (Sorden, 2008). IHC is used to confirm presence of PCV2 antigen within the histopathologic lesion. PCR has little value in diagnosing PCVAD unless the herd is considered free. Commercial vaccines are very effective and available with flex labels for administration to sows and pigs and as 1 or 2 doses (Chae, 2012). Nonvaccinated, subclinically infected pigs have poorer weight gain compared to their vaccinated counterparts (Kristensen *et al.*, 2011); therefore, it is part of most vaccination protocols by US pork producers (**Figure 4**).

PRRS is the result of infection with the Leylystad or North American strain of PRRSv. The estimated cost of PRRS to the US pork industry is US$664 million annually (Holtkamp *et al.*, 2013). PRRSv is the most commonly diagnosed viral respiratory pathogen at VDLs (Gauger, 2009). Infection is observed to increase susceptibility to other infections, particularly opportunistic bacteria. This apparent increased susceptibility to secondary and opportunistic infections is the result of the pathologic process in which PRRSv recruits and replicates in pulmonary alveolar macrophages, and then disseminates systemically (Rossow, 1998). Clinical signs are nonspecific including fever, lethargy, and dypsnea but not cough. Signs also depend on the type of secondary infection(s) present. Lungs fail to collapse and appear heavy, wet, and gray on postmortem examinations. Lymphadenopathy is caused by hyperplasia of germinal centers. Interstitial pneumonia, alveoli are lined with hyperplastic type II pneumocytes and contain necrotic debris, whereas the lining of bronchi and bronchioles is normal (Rossow, 1998). Vasculitis also occurs. PCR is the most sensitive method for confirming infection. Owing to the genetic diversity of PRRSv, sequencing of the ORF5 region is a common adjunct to PCR testing. Sequences are then used to create dendrograms for use by production systems pursuing PRRS control and epidemiologic investigations (Murtaugh, 2012). PRRSv ELISA is helpful for establishing herd status; National Animal Health Monitoring Service reports that a large percentage of US herds are seropositive. Treatment is limited to maintaining pig comfort, minimizing stress, and controlling secondary infections. Commercial modified-live vaccines (MLV) are available and administration during the nursery phase significantly reduces mortality and improves growth performance during the grow–finish phase of production (Robbins *et al.*, 2013b). MLV vaccines do replicate and should not be used in negative populations.

Figure 4 Pulmonary edema, lung, grow–finish pig. Interlobular edema associated with PCVAD, ventral portion of apical and diaphragmatic lung lobes is consolidated (purple) due to secondary bacterial infection. Courtesy Dr. Glen Almond.

Salmonella cholerasuis is the swine-adapted *Salmonella* from the C1 serogroup and, unlike *S.* Typhimurium, is not a foodborne pathogen. Ingestion or inhalation of the bacteria causes a septicemia resulting in low to moderate morbidity with high mortality within 1–2 days of infection that occurs postweaning, predominately during the grow–finish phase (Baskerville and Dow, 1973). Signs include high fevers ($>40\ ^{\circ}C$), lethargy, dyspnea, acute death, and cyanotic extremities and abdomen. The latter makes it impossible to differentiate clinically from classical swine fever virus (CSFv). Pleuropneumonia, interlobular edema, mediastinal, and tracheobronchial lymphoadenopathy, and occasionally white foci in the liver are apparent postmortem (Turk *et al.*, 1993). Acute histopathologic lesions that form in the lung are purulent bronchitis, lobular necrosis, and abscessation, whereas paratyphoid nodules are observed in the liver. Isolation is best achieved from the draining lymph nodes, lung, or liver using selective culture media. Serogrouping and typing is necessary for speciation and diagnostic confirmation. Owing to the rapid onset of disease, parental treatment is recommended. *Salmonella cholerasuis* isolates are commonly susceptible to ceftiofur. Increased hygiene particularly eliminating access to waste and vaccination is preventive (Husa *et al.*, 2009).

SIV is more accurately described as influenza, to encompass the infections occurring in swine, avian, and human species. Influenza virus is classified by its hemagglutinin and neuraminidase proteins; the three predominant strains in pigs are H1N1, H1N2, and H3N2. Rapid transmission and onset are characteristic; in the experimental inoculation of one nonvaccinated nursery age pig resulted in 10.66 more becoming infected (Romagosa *et al.*, 2011). Virus is shed for 3–5 days and uncomplicated lesions resolve 28 days postinfection (Gramer, 2007). Nasal discharge, fever, and lethargy occur but resolve quickly. Cough and dyspnea can last up to 2

weeks postinfection. PCR and VI detect virus for diagnosis of clinical cases. ELISA and HI detect antibodies; ELISA is helpful in establishing herd status, whereas HI is best for vaccination timing and measuring postvaccination titers (Allerson *et al.*, 2008). Necrotizing bronchitis, bronchiolitis, and alveolitis as lesion resolves affected areas appear vacuolated. Pigs recover quickly so treatment should focus on maintaining pig comfort, minimizing stress, and controlling secondary infections. All licensed vaccines are killed; commercial and autogenous products are in use in the United States. Vaccination reduces lung lesions and rate of transmission, but does not prevent infection and is complicated by antigenic shift and drift. In the United States, it is typical to vaccinate the sows rather than pigs to control disease and infection (Allerson *et al.*, 2013).

Diseases That Affect International Trade

Trade diseases are those listed by the OIE. When one of these diseases is suspected or confirmed, it results in closure of international market access, which would be economically devastating to import–export businesses. The primary method for managing diseases that affect trade is to prevent their introduction.

Foot-and-mouth disease (FMD) is caused by a picornavirus, FMDv, which causes mucosal lesions exclusively in cloven hoofed species. Clinical signs are excessive salivation, anorexia, and lameness causing high morbidity but low mortality. Gross lesions are vesicles at cutaneous junctions, on the snout, or in the oral cavity. Similar lesions can be caused by Seneca Valley virus, vesicular stomatitis, swine vesicular disease, and vesicular exanthema of swine; therefore, any blister in swine warrants diagnostic investigation. FMDv is highly transmissible within and between species.

African swine fever (ASF) is caused by ASFv, currently classified as an Iridovirus. Soft ticks can act as reservoirs or vectors. Current outbreaks are reported throughout Eastern Europe and Russia that have been associated with improper garbage feeding. The virus damages blood vessels resulting in clinical signs and gross lesions consistent with septicemia; including red to purple skin discoloration and enlarged spleen, liver, and lymph nodes. Excess blood and fluid in body cavities may occur.

Classical swine fever, historically referred to as hog cholera, is caused by CSFv, a pestivirus, eradicated from the United States in 1972. Transmission is associated with infected feeding, uncooked or undercooked garbage containing pork or pork by-products to swine. The virus remains infectious for months when refrigerated and years when frozen. Clinical signs are nonspecific and are easily confused with *S. cholerasuis*. The virus replicates rapidly in tonsils, which makes it the ideal tissue to collect for diagnosis of CSFv.

Glossary

Appellation A legally defined and protected geographical indication used to identify where the grapes for a wine were grown.
Chaptalization The process of adding sugar to unfermented grape must in order to increase the alcohol content after fermentation.
Chemometrics The science of extracting information from chemical systems by data-driven means.
Ecosystem A biological community of interacting organisms and their environment.
Geochemistry The science that uses the tools and principles of chemistry to explain the mechanisms behind major geological systems.
Jurisdiction The geographic area over which authority extends.
Plasticity The ability of an organism to change its phenotype in response to changes in the environment.
Topography The detailed description of the surface features of a region.
Transcriptome The set of all ribonucleic acid molecules produced in one or a population of cells (e.g., grape berries).
Véraison The onset of berry ripening (determined by the change in color or berry softening in red and white varieties, respectively).

Definition of the *Terroir* Concept

Terroir is considered a highly important concept in viticulture because it relates the sensory attributes of a wine to the environmental conditions in which the grapes are grown (Van Leeuwen and Seguin, 2006). *Terroir* can be defined as an interactive ecosystem, in a given place, including climate, soil, and the vine rootstock and cultivar (Van Leeuwen and Seguin, 2006), although human factors such as viticultural techniques and enological techniques may also be included (Seguin, 1986). The general assembly of the International Organization of Vine and Wine (OIV) recently adopted the broader definition for the descriptive use of the term *terroir* in viticulture and enology (Resolution OIV 333/2010; Anonymous, 2010). Vitivinicultural *terroir* is a concept that refers to an area in which collective knowledge of the interactions between the identifiable physical and biological environment and applied viticultural practices develops, providing distinctive characteristics for the products originating from this area. *Terroir* includes specific soil, topography, climate, landscape characteristics, and biodiversity features. The OIV resolution notes that the *terroir* concept is not to be confused with the legal definition of a Geographical indication (GI) used to describe viticultural production zones (Resolution OIV 333/2010), which are legally binding at the international level in both Old World and New World wine production regions (Anonymous, 2010).

History and Evolution of *Terroir*

Globalization of the international wine trade over the past 50 years has led to increasing production in New World countries with an emphasis on varietal and brand name wines and dominance of large companies (Rachman, 1999; Overton *et al.*, 2012). Concurrently, there has also been increasing interest, by both Old World producers in Europe and New World producers, in marketing wines from specific regions and localities to gain marketing advantages relating to source, heritage, control of winemaking, and perceptions that such wines are of higher quality (Gade, 2004). GIs are used to legally describe binding viticultural production zones (Resolution OIV 333/2010) with guidelines for zoning based on soil and climate characteristics established (OIV resolution 423/2012; Anonymous, 2012). In this context, the *terroir* concept establishes product individuality through an intimate connection between consumer expectation and the products offered (Gade, 2004), linking sensory attributes of wine to the environmental conditions in which the grapes are grown and processed (Van Leeuwen and Seguin, 2006). The first regions to be officially designated were the Chianti region in Italy in 1716, when four villages were recognized as the only producers of Chianti wines; the Tokaji (Tokay) region in Hungary in 1730 where vineyards were classified into three categories based on soil, sun exposure, and potential to develop noble rot, (*Botrytis cinerea*) (Wikipedia) and the Douro region in Portugal in 1756 (Cardosa, 2013).

The wine term, *terroir* appears to have first been applied in the fourteenth century in France to certain top-quality wine producing properties from the Cote d'Or in Burgundy (Whalen, 2009). Van Leeuwen and Seguin (2006) indicate that wine in the Bordeaux region of France was sold by the name of the Parish in the Middle Ages with the first estate wines sold in the seventeenth century. In the Bordeaux region, qualitative differences among wines produced led to a classification system being introduced in 1855 for wines from Medoc chateaux, which could be considered as *terroir* wines, as the grapes were exclusively from their own vineyards (Van Leeuwen and Seguin, 2006).

In the mid-1850s, winegrape production in Europe was almost annihilated due to the introduction of an aphid, Phylloxera, which attacks vine roots and the fungal diseases powdery mildew (oidium), downy mildew, and black rot from the Americas. This led to a complete restructuring of vineyards with the adoption of phylloxera-resistant rootstocks, derived from native American species, into solid management blocks, generally of the same variety, loss of varieties, and changes to management practices with the use of sulfur and copper-based sprays for fungal control (Gade, 2004; Whalen, 2009). Despite these significant changes in planting material and management practices the production of *terroir* wines from recognized vineyards in key regions has been maintained.

In France controlled appellation or place of origin labeling is the legal institution that mediates between the consumer and the producer and fixes the unique, place-based qualities of the product (Gade, 2004). The Appellation d'Origine Contrôlée (AOC) guarantees place of origin and lays out a set of production requirements for that bounded space identified with quality. Through appellation control, colloquial environmental space (*terroir*) becomes jurisdictional space (*territoire*), defined by its boundaries (Gade, 2004). In France, 'The Institut National des Appellations d'Origine', established in 1935, issues the decrees of local syndicates that meet certain requirements and implements quality standards with new AOCs added annually. It guarantees the consumer the authenticity of a region, the variety of grapes used, the vinification process, the maximum yield per hectare, and a defined level of alcohol (Lemaire and Kasserman, 2012) but does not specify climate, microclimate, and soil differences (Gade, 2004). Similar control of wine production, based on classification and regulation at the regional level exists in most European Union countries (Lemaire and Kasserman, 2012).

Over the past 50 years, with increasing globalization of the wine industry, traditional European winegrape producers have faced major issues of oversupply, increased production costs, increased awareness of environmental issues, and impacts of climate leading to well-documented changes in phenology and ripening (e.g., Jones, 2006) and shifts in consumer awareness and wine style. As a consequence, there has been significant changes in traditional European winegrape production to reduce production costs, with mechanization of harvest, pruning, canopy management, and new techniques for crop control (Intrieri, 2013); changes to soil management practices with the use of zero tillage, cover crops, and herbicides (Neethling *et al.*, 2013); adoption of integrated pest management and the use of new chemicals for the control of pest and diseases. There has also been significant adoption in many regions of modern winemaking techniques including the use of selected yeast strains rather than wild ferments, a subject beyond the scope of this treatise. Despite these major changes in the winegrape industry there continues to be strong support for the ongoing production and sale of *terroir* wines, an indication that the *terroir* concept is flexible and adaptable to change within a regulated framework (Gade, 2004).

New World wine producers, particularly in cooler, 'premium' regions have also shown a strong interest in establishing and marketing *terroir* wines from specific regions and localities to gain marketing advantages over large-scale commercial wines (Gade, 2004). Substantial research has been directed toward these aspirations. For example, in the Niagara Peninsular region of Ontario, Canada, sensory profiling of wines has been used to distinguish wines produced from the 'bench, plains, and lakes' viticultural areas for Riesling, Chardonnay, and the Bordeaux-style red varieties, Cabernet Sauvignon, Cabernet Franc, Merlot, and their blends (Douglas *et al.*, 2001; Kontkanen *et al.*, 2004), which have been linked to climate, topography, soil texture and water status, vine size, plant water status, and climate (Kontkanen *et al.*, 2004; Reynolds *et al.*, 2007; Reynolds *et al.*, 2013). In South Africa, natural *terroirs* have been identified in the Stellenbosch region based on homogeneous topography, climate, geological substrate and soil characteristics, vine growth characteristics, and fruit and wine composition of Cabernet Sauvignon and Sauvignon Blanc (Carey *et al.*, 2008; Carey *et al.*, 2009).

The strong international interest in the *terroir* concept is supported by the OIV definition provided in Resolution OIV 333/2010 embedded within the viticultural production zones (GIs, Resolution OIV 333/2010; Anonymous, 2010). Nonetheless, there is another school of thought, particularly in the popular press that the *terroir* concept is overrated and of little value to the modern wine industry. Rachman (1999) suggested that Europe should relax its wine laws, particularly with regard to the use of irrigation and alternative varieties, to take full advantage of modern technology, minimize seasonal fluctuations in quality to produce a consistent product, and adapt to consumer preferences. Gergaud and Ginsburgh (2008) concluded from a study undertaken in Bordeaux that *terroir* was of little importance and that technological choice including variety, vine age, and winemaking practices affect quality, based on international expert rating and price of wines, more than 'natural endowments' (land and soil). However, this study included very few parameters describing the 'natural endowment,' being limited to a crude soil description, soil nutrient content, altitude, and exposure (direction of the slope). In contrast, Vaudour (2002) indicated that scientific rigor can now be applied to update the *terroir* concept using integrated approaches that combine spatial modeling and geographical information systems (GIS) to describe the vineyard environment supported by modern technologies to measure grape and wine composition, enhanced approaches to sensory wine analysis and assessment of plant performance and physiology.

The Reality of *Terroir*

The *terroir* concept relates sensory attributes of wine to the environmental conditions in which the grapes are grown. It

embraces the key natural elements of climate, landscape characteristics, soil characteristics, and human factors (history, socioeconomics, selection of genotype, variety and rootstock selection, vineyard management practices, and winemaking technologies) leading to the production of unique, site-related, *terroir* wines (Van Leeuwen and Seguin, 2006). The relative importance of each element and their interaction will vary depending on the region and product style. In agreement with Vaudour (2002), Bodin and Morlat (2006) suggest that a rigorous scientific approach is required to validate the *terroir* concept. Integrated approaches involving the use of advanced climatic models, remote sensing, and new technologies to measure soil characteristics, aspects of vine physiology, fruit and wine composition and qualitative sensory analyses in combination with spatial modeling, GIS and multivariate data analysis are being used to validate the *terroir* concept and identify the relative importance of the various components. Furthermore, the understanding of *terroir* is also being enhanced through the use of molecular techniques. For example, measurements of the grapevine berry transcriptome of Corvina grown in the Verona region of Italy have reported seasonal effects of the environment on the expression and function of genes based on clustering of transcripts and groupings of vineyards sharing common viticulture practices and environmental conditions (Dal Santo *et al.*, 2013).

Climate and *Terroir*

Climate is considered to be the most important component of *terroir* as it largely determines the suitability of a region to different winegrape cultivars, their growth and production, the overall wine style, and vintage variability (Jones *et al.*, 2012). Differences in wine quality ratings across vintages can be attributed to seasonal differences in climate (Jones, 2005). The importance of climate to the expression of *terroir* was clearly shown in a study conducted in Bordeaux, where the impact on fruit quality parameters of soil, climate (vintage), and variety (Merlot, Cabernet Sauvignon, and Cabernet Franc) were studied simultaneously (Van Leeuwen *et al.*, 2004). Climate (vintage) was the dominant factor accounting for a high proportion of the variation in fruit composition (total acidity 70%, pH 73%, and anthocyanins 41%).

Jones *et al.* (2012) indicated that the influences of climate on *terroir* should be considered at the macroscale (synoptic climate), the mesoscale (regional climate), the toposcale (site climate), and at the microscale (vine row and canopy climate) taking into account the weather and climate structure for optimum quality and production; the climate suitability of different cultivars; the climate variability in a region; and the influence of climate change. Important components of the climate that influence vine growth, production, and fruit composition include solar radiation, which may be impacted by vineyard topography (slope and aspect), day length, cloud cover, reflective nature of the soil, the average temperature over the growing season, the day–night temperature difference, temperature extremes (i.e., winter freeze, frost, and summer heat stress), heat accumulation, wind, precipitation, and humidity (Jones *et al.*, 2012).

It has been suggested that wine regions have developed over time to best match their regional environmental conditions, allowing for generally consistent ripening of varieties that are best suited to the conditions (Jones, 2006). For wine production, the average temperature during the growing season ranges from 13 to 21 °C (Jones *et al.*, 2012). Maturity groupings have been developed to match the suitability of a variety to a regional climate based on average growing season temperature, i.e., cool (13–15 °C), intermediate (15–17 °C), warm (17–19 °C), and hot climate (19–21 °C) (Jones, 2006). Such groupings suggest that varieties could be grown in climatic regions where they are not currently grown in Europe and that current locations are historical and influenced by other human factors (e.g., trade, wine style preferences, etc.). Indeed, many of the varieties are not ideally suited to their region as chaptalization (addition of sugar) is required in many vintages to provide adequate levels of alcohol in the wine, although this requirement is decreasing as temperatures have increased over the past 50 years (Jones *et al.*, 2012).

Modern spatial analysis tools are providing methods to incorporate a wide range of climatic variables in the regional analyses of climate. Bioclimatic indexes describing the suitability of a particular region for winegrape production are a widely used zoning tool (Jones *et al.*, 2011). They used gridded data of temperature and precipitation to compute three of the indexes (i.e., the Winkler and Huglin degree day indices and a composite suitability index, Malheiro *et al.*, 2010) for Europe to study interannual variability (1950–2009). They conclude that strong regional contrasts were clearly apparent in the different index patterns, creating a wide range of local conditions that largely explain the quality and diversity of the winegrape growing regions across Europe. Furthermore, Bois *et al.* (2012) conducted a high resolution climate spatial analysis of European winegrowing regions across 260 regions in 18 countries at a 1 km resolution incorporating a wide range of climatic variables including the Huglin Index, the cool-night index, a dryness stress index, a heat stress index, winter freeze, and spring frosts risk. Clustering analyses of common characteristics were used to identify six climate types across Europe, not necessarily located in a particular region, to better depict the climatic components of *terroir*.

Geology, Soil, and *Terroir*

Winegrape production in Europe generally occurs on poor soils, not suited to other agricultural pursuits (Van Leeuwen and Seguin, 2006). The term *terroir* implies links between land and soil and wine quality. This ideology is pursued by Wilson (1998) who suggested that quality winegrapes are grown on a diverse range of soils and that each soil type contributes its own characteristics and mouthfeel to a given variety. For example, associations between the 'flint' character of Chablis wines and 'gunflint' character of Riesling and flint, shale, and slate bearing soils are reported (Huggett, 2006). However, there is very little scientific evidence to support such a connection. Indeed Maltman (2008, 2009) in reviewing the relationship between geology and wine concludes that any suggested link between geology (bedrock composition, soil mineralogy, and geochemistry) and wine flavor can be nothing more than a romantic myth. A view supported by detailed multivatiate *terroir* studies involving chemical and sensory wine analyses conducted by Cadot *et al.* (2012) in the Loire

valley of France with Cabernet Franc and Cabernet Sauvignon showed that bedrock type was not significant whereas the proportion of the varieties, harvest date, alcohol level, and winemaking practices were significant factors. Perceived saltiness in wines from specific regions, for example, the Manzanilla region of Spain which is close to the sea, may be an example where a direct linkage between the soil and a wine quality attribute can be made (Huggett, 2006), a view supported by studies where the salt content of wines has been shown to affect wine taste (Walker *et al.*, 2003).

Studies across a wide range of typical Bordeaux soil types (i.e., alkaline limestones, acidic gravels, neutral gravels, or heavy clay) indicate that soil type had no definite influence on the quality of harvests and wine quality of *terroirs* although certain *terroirs* consistently produced better wine in all seasons (Seguin, 1986; Van Leeuwen and Seguin, 2006). The soil effect on *terroir* can be better explained by the physical properties of the soil and their consequences for root development on regulation of water supply and nutrients to the vine. Seguin (1986) also noted that human factors such as soil cultivation, provision of drainage, and rootstock selection added further complexity to the issue. Van Leeuwen and Seguin (2006) indicate that the best expression of *terroir* is achieved, at least for red wine, when full ripeness is achieved at the end of the season from vines with moderate vigor. They describe the importance of root zone temperature associated with soil type (i.e., drier soils have higher soil temperature than wetter soils). In detailed studies across vintages, soil types and varieties in Bordeaux, Van Leeuwen *et al.* (2004) established strong links between soil and vine nutrition, plant water relations, vine growth, and berry composition. Soil type accounted for variances in predawn leaf water potential (40%), berry potassium content (32%), anthocyanins (30%), yield (32%), pruning weight (28%), vine nutrient status (petiole nitrogen, potassium, and magnesium, 24%, 42%, and 75%, respectively), must sugar (32%), and anthocyanins (32%). Huggett (2006) also noted the importance of drainage and water holding capacity and raised the issue of soil color for absorption of incoming radiation, leading to higher soil temperatures and night reradiation to reduce frost risk. Renouf *et al.* (2010) produced high resolution soil maps for prestigious vineyards in the Bordeaux area, which confirmed the importance of soil type, rootstock selection, and varietal selection on fruit quality, based on a quality index determined from fruit destinations over five vintages. Coipel *et al.* (2006) found that soil depth was more important than soil type in describing the *terroir* effect for Grenache vineyards in the Cotes du Rhone region of France. Grapes with the highest potential for making quality wine (i.e., those with lower yields, higher sugar, and anthocyanins) were obtained on soils with the lowest water holding capacity.

Bodin and Morlat (2006) developed a concept of basic terroir unit (BTU) to provide scientific rigor into zoning of *terroirs*, determined from soil depth and the degree of weathering of the underlying rock to account for soil effects on wine water supply, growth, and phenology. A BTU is defined by Goulet and Morlat (2011) as a ''territory with homogeneous vine behavior from a view point of ecophysiological conditions, as well as a sufficient area to make it agronomically and commercially worthwhile for viticulture.'' BTU maps that combine soil measurements and aerial photographs provide useful information on soil water, potential for early growth and vigor to assist growers in their choice of soil management, rootstock, and weed control. Validation studies for the use of BTU maps showed that soils with strongly weathered rock produced smaller berries with higher sugar, anthocyanins and phenolics and more aromatic wines associated with differences in plant water relations, timing of budburst, soil water, yield, canopy density, and pruning weight (Bodin and Morlat, 2006).

Measurement of soil electric resistivity provides a tool to rapidly assess available soil water holding content and potential root activity in studies of *terroir* (Goulet and Barbeau, 2006). Other soil parameters related to *terroir* include soil nitrogen status because of potential indirect effects on vine vigor and yeast assimilable nitrogen (Reynard *et al.*, 2011; Van Leeuwen *et al.*, 2011; Van Leeuwen and Seguin, 2006).

Plant Water Status and *Terroir*

Irrigation is prohibited in many European vine growing regions. Consequently, water holding capacity of soil is considered an important component of *terroir* and vintage effects of climate because of related effects on plant water status, vine vigor, phenology, and fruit composition (Van Leeuwen and Seguin, 2006). In Hungary, Zsofi *et al.* (2009) found strong relationships between plant water status, yield, and wine quality parameters and suggested that measurement of stomatal conductance and predawn leaf water potential provided reliable parameters for *terroir* classification across varying vintages. Moderate stress found on sloped vineyards compared with vineyards with higher water availability produced berries with higher sugar levels, anthocyanins, and phenolics associated with lower yields and better canopy and fruit exposure. In further studies Zsofi *et al.* (2011) showed that the enhanced sugar levels of berries from the moderately stressed vines was independent of berry size, despite lower levels of photosynthesis. Rezaei and Reynolds (2010) observed a strong link between vine water status and sensory characteristics of Cabernet Franc in Canada and also suggested that measurement of midday leaf water potential could be used for classifying the *terroir* effect across wet and dry seasons.

Van Leeuwen and Seguin (2006) recognized that measurements of plant water status can be important tools in *terroir* studies in regions such as Bordeaux noting that wines from moderately stressed vineyards are generally preferred, particularly for red wines, whereas severe stress may reduce aroma potential of white wines. For red wines, Tregoat *et al.* (2002) were able to describe differences across Merlot vineyards in Bordeaux based on measurements of plant water status (predawn water potential, stem water potential, and carbon isotope discrimination). They observed that vineyards with moderate water stress had early cessation of growth and produced smaller berries with improved composition (i.e., higher sugar levels, anthocyanins and phenolics and reduced malic acid levels). For Sauvignon Blanc vineyards in Bordeaux, vine vigor could be linked to vine water status and nitrogen status (Peyrot des Gachons *et al.*, 2005). Vines under severe water stress produced small berries with low sugar and limited aroma potential compared with mild water deficits. Their

results indicated potential to use targeted irrigation for Sauvignon Blanc in dry seasons. In Greece, Koundouras *et al.* (2006) were able to correlate predawn water with sensory assessments of the red variety Agiorgitiko across different sites. Differences in vine water status were highly correlated with cessation of shoot growth and earliness of véraison with stressed vines giving wines with higher levels of anthocyanins, phenolics, and aromatic characteristics, which were preferred in sensory assessments.

Van Leeuwen *et al.* (2001, 2011) suggested that carbon isotope discrimination in berries, which correlated with predawn water potential, can be a useful tool for use in *terroir* studies for assessing vintage and soil type effects, as it is an integrative indicator of vine water deficits during the ripening period. Similarly, in Switzerland, Reynard *et al.* (2011) found a strong correlation between carbon isotope discrimination measurements in berries and soil water holding capacity across three seasons and 23 sites. Mild deficits produced smaller berries with higher sugar levels and wines with higher color density. Similarly, for Sangiovese in Italy, strong relationships with carbon isotope discrimination measurements were found with soil water holding capacity, vine water status, and related effects on berry anthocyanins and must acidity (Costantini *et al.*, 2010).

Terroir Validation by Modern Sensory and Analytical Techniques

To be accredited as a *terroir* wine in the French AOC system it must show typicality (typicity; Cadot *et al.*, 2010). A range of modern sensory techniques using sensory profiles, sorting and ranking methods, and qualitative descriptions are now being used to give credence to *terroir* wine classification in protected regions (Cadot *et al.*, 2010; Etaio *et al.*, 2010; Maitre *et al.*, 2010). For example, Cadot *et al.*, 2010 used quantitative descriptive analysis by a sensory expert panel to discriminate between *terroir* wines of Cabernet Franc and Cabernet Sauvignon in the Loire Valley. Similarly, Segurel *et al.* (2009) were able to discriminate *terroirs* for Grenache and Shiraz in the Rhone valley by quantitative descriptive analysis.

Enhanced analytical techniques of fruit and wine, in combination with advanced chemometric techniques is providing underpinning evidence to support the *terroir* concept. For example gas chromatography mass spectrometry (GCMS) techniques for the analyses of volatiles associated with wine aroma and flavor compounds together with sensory evaluation have been used to discriminate between vineyard plots of Gewurtztraminer in Alsace (Diminger *et al.*, 1998), Grenache Noir in the Rhone Valley vineyard, a study that highlighted the importance of soil water holding capacity, early maturation, and must sugar content across the *terroirs* (Sabon *et al.*, 2002). Furthermore, in Australia sensory and chemical analysis, including GCMS analysis of volatiles, has been used to describe spatial variability at the within vineyard scale (Bramley *et al.*, 2011a), potentially adding further precision to the concept of *terroir*.

Other chemical methods used to validate the *terroir* concept include high-performance liquid chromatography anthocyanin analysis in Bordeaux, which showed impact of variety on *terroir* (De Gaulejac *et al.*, 2001), spectroscopy (ultraviolet/visible/near-infrared spectral analysis) in combination with chemometric tools, which was used to discriminate and authenticate subzones in the Rias Baixas region of Spain (Martelo-Vidal *et al.*, 2012), measurement of stilbenes (Tomasi *et al.*, 2013) and soil active lime (Gatti *et al.*, 2011) in Italy, NMR spectroscopy, which was used to distinguish varieties, vintages, and soil type in Bordeaux (Pereira *et al.*, 2006) and linked with soil characteristics (levels of carbonate, clay, and organic matter) across Italian Aglianico vineyards (Mazzei *et al.*, 2010). In Argentina, Di Paola-Naranjo *et al.* (2011) used analyses of inorganic and organic compounds and stable isotope analyses to match soil provenance using chemometrics and differentiate *terroirs* and varieties.

Classification of *Terrior* Using Geographic Information Systems with Multivariate Statistics

Modern multivariate statistical approaches in combination with GIS are now being used to improve zoning and *terroir* classification through the identification of homogenous terroir *units* (Gomez-Miguel *et al.*, 2013). Such studies may include combinations of high resolution climate data, geological and soil data and information on topography, altitude, variety and rootstock, vineyard management factors, fruit composition and product type (Gomez-Miguel *et al.*, 2013), a topography index (Herrera-Nunez *et al.*, 2011), the Huglin and Winkler bioclimatic indexes (Ince *et al.*, 2013; Jones and Alves, 2013), simulated plant water balance models and crop water stress indexes (Bonfante *et al.*, 2011), a categorized maturity index (Fraga *et al.*, 2013), and fruit composition (Gonzalez-Centeno *et al.*, 2012). Such approaches have been used to identify the key factors contributing to *terroir* effects and improve the *terroir* classification in the Douro region of Portugal (Gomez-Miguel *et al.*, 2013; Jones and Alves, 2013; Santos *et al.*, 2013), the Balearic islands of Spain (Gonzalez-Centeno *et al.*, 2012), the Loire valley of France (Cadot *et al.*, 2012), and in Italy, the Montepulciano d'Abruzzo region (Nunez *et al.*, 2011), Primitivo vineyards in the Apulia region (Ince *et al.*, 2013), and vineyards in the Campania region (Bonfante *et al.*, 2011). There is no doubt that such studies in the future will add further scientific rigor to both an understanding of the *terroir* concept and to enhance *terroir* classification.

Integration of *Terroir* with Modern Viticultural Practices

Low-Input Integrated Viticulture and *Terroir*

Integrated strategies of vineyard management, based on mechanization are widely adopted by winegrape producers in New World countries such as Australia (Clingeleffer, 2010; Clingeleffer, 2013) and increasingly in Europe (Intrieri, 2013). White *et al.* (2009) considered that the concept of *terroir*, although not easily reconciled with mechanization, must retain flexibility to keep the concept alive and meet challenges from New World producers and impacts of climate change. Clingeleffer (2010) provided an overview of approaches to integrated vine management available to enhance the consistency of supply and wine quality attributes over vintages, in

a low-input context. These integrated approaches include lighter pruning (mechanical hedging, minimal pruning, and mechanization of cane pruning based on high-cordon systems); application of crop control techniques other than winter pruning such as prebloom basal leaf and postset mechanical thinning; improved irrigation practices such as regulated deficit irrigation, prolonged deficits, and partial root zone drying; the use of low-moderate vigor rootstocks and high-density plantings. Adoption of all of these technologies may not be immediately applicable in traditional *terroir* vineyards as they may require changes to the regulatory framework (e.g., the use of irrigation in some regions). However, the widespread adoption of mechanical harvesting is an indication of the flexibility of *terroir* wine producers and the regulatory environment to accommodate change as management practices evolve to meet both the challenges of globalization and climate change. Future change and vineyard adaptation will be underpinned by the significant research effort in Europe, which aims to develop economically sustainable management practices and maintain or enhance wine quality attributes.

It is generally recognized that the traditional forms of management in Europe, based on systems involving vertical shoot positioning (VSP) not only have a high input requirement, particularly of labor, but also are suboptimal with regard to vine performance and wine quality (Carbonneau and Ojeda, 2011; Intrieri, 2013). From their studies in France with a diverse range of trellis/canopy management practices, Carbonneau and Ojeda (2011) concluded that the wide trellis lyre system (a form of U-trellis) and minimal pruning were optimum from a sustainability perspective based on canopy and berry exposure, use of the soil space, effects on water stress, soil management, energy, and carbon costs whereas the traditional, VSP systems rated poorly. Intrieri (2013) provided an overview of Italian research aimed at integration of mechanization with vineyard training and management to optimize yield and wine quality. Developments include permanent cordon trellis systems, including double-curtain wide U-trellises, which may be hand and machine pruned to replace the high input standard forms of cane pruning using guyot, sylvoz, and arched cane training. Refinements of these systems include the use of free cordon systems without shoot positioning, semiminimal pruning, improved crop regulation by early mechanical thinning of shoots, mechanical crop thinning prevéraison and basal leaf defoliation preflowering to reductions in yields, cluster compactness and botrytis rot, and the use of post-véraison antitranspirant sprays or canopy reduction by trimming to delay ripening.

In Europe, there is considerable interest in lighter pruning systems, which if integrated with mechanized yield regulation should be compatible with *terroir* wine production. Such approaches should also reduce the year to year variation in yield associated with climatic effects on fruitfulness and crop development (Clingeleffer, 2010). Beneficial attributes associated with lighter pruning systems adopted in Australia include development of vines with small, well-exposed bunches of small berries, spread over a large canopy surface, which lead to good disease control and improved berry composition, provided adequate sugar levels are reached (Clingeleffer, 2010). Compared with severe forms of pruning, minimally pruned vines generally produce juice with better organic acid composition, expressed as a superior tartrate to malate ratio, better wine color, and higher phenolics (Clingeleffer, 2010). Studies conducted in Europe generally support these results. For example, mechanical pruning has also been applied successfully to vertically shoot positioned Alfrocheiro vines, a red variety, in the premium Douro region of Portugal without effects on fruit composition and wine quality despite a doubling in yield (Cruz *et al.*, 2011). In long-term studies conducted in the Languedoc-Roussillon of France across a range of varieties, Rousseau *et al.* (2013a) observed that minimal pruning gave satisfactory results, except with late ripening varieties. Compared with standard management, minimal pruning at the same level of sugar had lower pH and more tartaric acid, and, although color and phenolics were lower, produced wines with sensory profiles preferred by consumers (i.e., less intense wines with more fruit driven and less herbaceous characters). Wine sensory profiles of both red and white varieties were also more stable across seasons. Similarly, for Riesling and other white varieties grown in a very cool climate in Germany, minimal pruned vines compared with those grown on a standard vertical shoot positioned system had higher yields (25–75%), looser clusters, and smaller berries with higher concentrations of aromatic precursors (Schultz and Weyand, 2005). This was reflected in enhanced sensory perceptions, despite having slightly lower levels of sugar.

To facilitate compatibility of modern management practices with the *terroir* concept there is considerable interest in Europe in mechanical and chemical techniques for yield regulation by removal of shoots, berries, inflorescences, and bunches. Gibberellic acid treatments have been successfully applied to reduce crop load and subsequent fruitfulness of minimal pruned Riesling in Germany while maintaining the quality benefits associated with minimal pruning, i.e., reduced bunch rot and enhanced flavor and aroma characteristics (Weyand and Schultz, 2006). Vertical rotational string thinners have also been used in Germany for early season shoot thinning of minimal-hedged vines (Schwab and Greber, 2013). One of the most promising techniques for crop regulation, which has been successfully tested across Europe, is the preflowering basal leaf removal which can be easily mechanized (Poni *et al.*, 2006, 2008; Intrieri *et al.*, 2008). This technique reduces fruit set and bunch compactness resulting in reduced incidence of bunch rots and improvements in fruit and wine composition. The technique has successfully been applied across a range of red and white wine varieties and regions in Italy, Portugal, and Spain (Diago *et al.*, 2013; Freire *et al.*, 2013; Moreno *et al.*, 2013; Queiroz *et al.*, 2011; Silva *et al.*, 2013; Taradaguila *et al.*, 2010, 2012). Postset mechanical thinning, which provides a final opportunity to adjust crop load after fruit set and before véraison has also been assessed in Italy and Spain (Diago *et al.*, 2013; Hanni *et al.*, 2013; Intrieri, 2013; Taradaguila *et al.*, 2008).

Precision Viticulture and *Terroir*

Over the past decade, techniques for rapid geospatial data acquisition, analysis, interpretation, and visual presentation have become available to characterize spatial variability within

a vineyard with regard to topography, soil characteristics, vine phenology, vigor and yield, and basic fruit quality attributes (Bramley, 2010; Johnson *et al.*, 2012; Green, 2012). Informed site-specific management decisions based on this knowledge is termed precision viticulture (Johnson *et al.*, 2012). Rapid site-specific data acquisition to facilitate adoption of precision viticulture includes remote sensing from satellite or aircraft to estimate vine vigor and health, ground-based mapping of soil characteristics, yield monitoring using harvester mounted devices and potentially, on-the-go sensing techniques of fruit quality attributes, (e.g., anthocyanins and phenolics, Bramley *et al.*, 2011b; Tisseyre, 2013). Furthermore, remotely sensed data have been linked to grape phenolics and color (Lamb *et al.*, 2004), berry sensory data (Rousseau *et al.*, 2013b), vine water status (Pons *et al.*, 2013), and incidence of ion chlorosis (Gonzalez-Flor *et al.*, 2013).

Bramley and Hamilton (2004) questioned the compatibility of the traditional *terroir* concept with precision viticulture where mandated management practices are applied at a regional level in designated GI zones in Europe whereas precision viticulture focuses on site-specific management. They concluded that the enhanced understanding provided by precision viticulture on the relationships between soil and land attributes on grape and wine production will provide a basis to impose management practices to gain greater control over fruit and wine quality and manage some of the elements of *terroir*.

High variability in vine vigor, yield, and fruit composition has been described in both New World vineyards (Bramley and Hamilton, 2004, 2007; Bramley, 2005) and in traditional European vineyards (Johnson *et al.*, 2012; Rousseau *et al.*, 2013a; Tisseyre *et al.*, 2007; Tisseyre, 2013). Bramley *et al.* (2011a) showed that variation in the chemical composition of grapes, wine, and sensory attributes could be linked to variation in vigor, yield, vine nutrient status, topography, and vineyard soil properties. Reynolds *et al.* (2007) demonstrated that the tools of prevision viticulture could be used to elucidate the basis for *terroir* based on vine size, fruit composition, soil texture, and wine sensory attributes.

Adoption of precision viticulture by traditional producers of *terroir* wines is likely to be highly varied depending on the region, wine style, and consumer expectations and may require changes in legislation in regulated GI regions. Nonetheless, there is strong interest in precision viticulture in Europe to manage production system complexity and provide information to more efficiently manage microscale variability for enhanced quality, yield, and revenue (Johnson *et al.*, 2012). Commercial services are emerging to provide decision support based on acquired geospatial data (De Filippis *et al.*, 2013; Rousseau *et al.*, 2013b). Adoption of precision viticulture by *terroir* wine producers is likely to fall into three main categories. These include the following:

Maintain the *Status Quo*

Maintenance of the *status quo* is an option based on the belief that the site-specific heterogeneity (i.e., in vigor, yield, ripeness, and fruit composition) is unique to the vineyard and thus a component of the *terroir*, which adds complexity to the wine.

Zonal Management

Precision viticulture techniques have been applied to identify zones within a vineyard for targeted vineyard and wine quality management (Proffitt *et al.*, 2006; Bramley, 2010). Targeted management techniques to improve vineyard homogeneity, largely addressing differences in vine vigor and fruit composition, include vineyard design and establishment based on soil characteristics, irrigation scheduling, soil and sward management including application of mulch (Newson and Nettelbeck, 2013; Newson *et al.*, 2013), choice of cover crop (Panten and Bramley, 2011), canopy management (Panten and Bramley, 2012; Newson and Nettelbeck, 2013), fertilizer management (Newson and Nettelbeck, 2013), and pest and disease management (Newson and Nettelbeck, 2013; Newson *et al.*, 2013). It is likely that a range of vine vigor control techniques such as lighter pruning in conjunction with various forms of crop regulation and where appropriate, use of rootstocks with varying levels of conferred scion vigor and adoption of enhanced deficit irrigation practices (Clingeleffer, 2010) will form part of integrated management strategies to improve homogeneity of vineyards producing *terroir* wines.

Benefits from the use of selective harvesting based on within vineyard zoning, either in real time or at different dates, have been shown to be a feasible and profitable strategy (Bramley *et al.*, 2005; Bramley *et al.*, 2011c). Such approaches provide options for improved harvest planning (Rousseau *et al.*, 2013a), batching, streaming and blending of fruit and wine, and production of different winestyles (Newson *et al.*, 2013; Bigot *et al.*, 2013a,b).

Variable Rate Technologies

There is significant interest, particularly in Europe, in the use of variable rate technologies (VRT) to refine precision viticulture to improve vineyard homogeneity compared with the coarse zonal management described above. Aspects of viticultural managements amenable to VRT include fertilizer application, soil cultivation (e.g., tillage depth), pest and disease management, weed management, mulching, irrigation supply, and canopy management (pruning, shoot thinning, leaf removal, and summer trimming; Johnson *et al.*, 2012; Vieri *et al.*, 2013).

Impact of Climate Change on *Terroir*

Climate projections for wine-producing regions are an increase in temperature of 0.5–1 °C by 2025 and approximately 2 °C by 2050, reduced rainfall, increased variability between seasons with increased occurrence and severity of extreme climatic events such as heat waves and drought (Jones *et al.*, 2012; Webb *et al.*, 2011). It is probable that current plantings will be influenced by future long-term climate changes as the economic life of a vineyard may exceed 40 years (Neethling *et al.*, 2013; Webb *et al.*, 2011). Predicted impacts of climate change on winegrape production include changes in phenology and ripening under warmer conditions, disruption of balanced composition in grapes and wine, alterations in

regional winestyles, and spatial changes in viable grape-growing regions (Holland and Smit, 2010; Jones, 2005; Ollat *et al.*, 2011; Jones *et al.*, 2012). Changes in climate will directly alter *terroir* and challenge the adaptive capacity of the industry, particularly in Europe where production practices are highly regulated and controlled by legislation. Such projections are likely to have serious consequences for regionality, in particular *terroir* because of the tight linkage between climate, soil, and adoption of varieties suited to premium wine production (Holland and Smit, 2010; Webb *et al.*, 2007a). Indeed, Hannah *et al.* (2013) predicted that the area suitable for viticulture in the major producing regions will decrease by 25–73% by 2050 without adaptation. As a consequence, shifts in the production base to higher elevations and higher latitudes are predicted (Hannah *et al.*, 2013; Neethling *et al.*, 2013; Duchene *et al.*, 2010; Malheiro *et al.*, 2010). Webb *et al.* (2007b) suggest that major shifts in the production base are unlikely because established regions have substantial investment in physical and social infrastructure, brand recognition, and in the case of many European vineyards, a history and recognition based on regionality and *terroir*. Consequently, grower adaptability to changing conditions will be critical for the maintenance of viticulture in existing regions and *terroirs* (Ollat *et al.*, 2011; Neethling *et al.*, 2013) and will require the cooperation of appellation boards and regulators (Pincus, 2003; Ollat and Touzard, 2013).

The dire predictions of Hannah *et al.* (2013) regarding the impacts of climate change on the suitability of the main producing regions appear to be overstated as the study did not account for the plasticity of varieties across temperature regimes and underestimate the adaptive capacity of viticulture management to warmer conditions (Van Leeuwen *et al.*, 2013). Furthermore, Hannah *et al.* (2013) did not include assessment of the significant body of research conducted in hot climates, which provides direction for adaptation by the industry in cooler regions. Schultz (2011) used Riesling and Cabernet Sauvignon as examples to demonstrate the climate adaptability of grapevine varieties (plasticity). He showed that these varieties are already grown internationally under very different climatic conditions in regions recognized for high-quality wine production, which exceed changes predicted by models of climate change. Furthermore, there is general agreement in the literature that the increase in temperature over the last 50 years over most winegrape regions, on average 1.3° (Jones *et al.*, 2005), has had a positive effect on wine quality associated with reduced year-to-year variation, longer and warmer growing seasons, less frost risk, and earlier and more consistent ripening conditions (Jones *et al.*, 2005; Jones *et al.*, 2012; Van Leeuwen *et al.*, 2013) except in hot production regions (Webb *et al.*, 2007b, 2008). However, it is predicted that with higher temperatures many varieties may be grown outside their optimum threshold temperature limits (Jones *et al.*, 2012; Holland and Smit, 2010).

Ollat *et al.* (2011) stressed the importance of developing adaptation strategies to assist the industry to cope with climate change particularly for the most at risk, warm and dry Mediterranean regions and by implication *terroir*, in Europe. Viticultural strategies suggested include use of noncompetitive interrow grass swards to minimize soil evaporation, targeted adoption of irrigation (i.e., when evaporative demand is high and water availability is low), canopy cooling by misting, shading, and canopy configuration. Neethling *et al.* (2013) reported that growers in the Loire valley in North West France have already made significant adaptive changes over the last 20 years, particularly in soil management. These adaptive changes include the use of less competitive cover crops, modifications to canopy management and rootstock choice to cope with warmer conditions and drier soils. They also indicate a willingness by growers to consider the introduction of new varieties and irrigation currently not allowed in the region. Ollat *et al.* (2011) indicated that breeding to develop new varieties and rootstocks with improved heat tolerance, drought tolerance, and water use efficiency must be a critical part of this strategy to maintain production in existing regions.

Research undertaken in hot regions provides further direction to develop and underpin adaptation strategies to increasing temperature and water stress. For example, vineyard management research conducted in a hot climate overviewed by Clingeleffer (2010) described opportunities to develop strategies to enhance the consistency of supply and wine quality through integration of lighter pruning, crop regulation, and irrigation practices together with adoption of low-moderate vigor rootstocks (see Section Low-Input Integrated Viticulture and Terroir). Further studies confirm that rootstocks are a powerful tool to manipulate growth characteristics, fruit composition and wine quality attributes, water use efficiency, and drought tolerance in hot climates (Clingeleffer *et al.*, 2011).

There is also considerable interest in Europe in the use of postvéraison leaf removal by trimming to delay ripening as an adaptive strategy to climate change (Filippetti *et al.*, 2011; Intrieri, 2013; Lanari *et al.*, 2013; Palliotti *et al.*, 2013; Pisciotta *et al.*, 2013; Rombola *et al.*, 2011; Stoll *et al.*, 2013). Furthermore, ripening has also been successfully delayed using antitranspirants (Filippetti *et al.*, 2011; Palliotti *et al.*, 2011). Technologies to reduce fruit and canopy temperatures may also offer significant benefit to facilitate ongoing production from high value regions and *terroirs*. They include particle film technology (Glenn *et al.*, 2010), artificial shade, and water misters (Ollat *et al.*, 2011).

Exploitation of genetic diversity is considered a critical component of adaptation to climate change. This will include sourcing of varieties successfully managed in warm and hot climates and breeding new varieties with more intense flavor, better color, lower pH, and improved acidity and organic acid composition with improved water use efficiency and drought tolerance (Ollat *et al.*, 2011; Ollat and Touzard, 2013; Webb *et al.*, 2011). Clingeleffer *et al.* (2013) described systematic studies that aimed to phenotype 500 varieties grown in a hot climate for traits considered important to climate change adaptability. These included optimal fruit composition with respect to total soluble solids, titratable acidity, pH, organic acid composition, total anthocyanins and phenolics, and flavor; varieties with high water use efficiency based on short seasonality and high fruit-to-leaf ratios; and varieties to extend the harvest period. The study showed significant potential to adopt a wider suite of varieties to facilitate adaptation by industry to meet future climate change scenarios. As mentioned above, the cooperation of appellation boards and regulators

will be required to permit *terroir* winegrape production from a wider spectrum of varieties (Pincus, 2003; Ollat and Touzard, 2013).

Conclusions

The *terroir* concept, which provides a link between the sensory attributes of a wine and consumer expectations and the environmental conditions in which the grapes are grown, evolved in European viticulture over many centuries. Evolution of the *terroir* concept has involved significant changes to vineyard management to accommodate challenges from pests and diseases, globalization of the winegrape industry with competition from New World producers and changes in consumer preferences, an indication that the *terroir* concept is flexible and adaptable to change within a regulated framework (Gade, 2004). There continues to be strong support for the ongoing production and sale of *terroir* wines with significant adoption of the concept in the New World by producers seeking marketing advantages over larger companies and blended products. The industry and regulators must embrace change and retain flexibility to meet future challenges associated with maintaining international competitiveness, environmental sustainability, climate change, and shifting consumer expectations. The challenge will be to keep the *terroir* concept alive, retain flexibility yet preserve the cultural connection between winemakers, the land and consumers (White *et al.*, 2009). This will be critical to the economies of historical *terroir*-based regions reliant on the significant investment in winegrape production and processing and established social infrastructure for survival (Ollat *et al.*, 2011).

New scientific tools are now available to integrate conceptually all the factors relating to *terroir* to enhance the understanding, accurately define zones, and provide guidance for vineyard management. These integrative tools include multivariate statistical analyses, geographic information systems (GIS) with high resolution climate and spatial modeling, rapid data acquisition of soil and plant characteristics to define the vineyard environment and modern technologies to measure grape and wine composition and wine sensory attributes. A suite of vineyard management practices and tools associated with precision viticulture, alternative varieties, and rootstocks are available to develop integrated approaches to facilitate adaptability by producers and ensure both the survival and future evolution of the *terroir* concept in modern viticulture. This will require flexibility by both producers and those involved in developing the future regulated legal framework for the production of *terroir* wines.

Glossary

Agrobacterium-mediated transfer-deoxyribonucleic acid (T-DNA) delivery A technique that uses strains of *Agrobacterium tumefaciens* that have been modified to transfer transgenes into plant cells.

Cisgenics Transformation using a perfect copy of an allele within or between sexually compatible species or moving an allele to a new genomic position within or between sexually compatible species.

Direct DNA delivery A range of techniques for introducing either linear single- or double-stranded DNA fragments or plasmids into plant protoplasts, cells, or tissues using physical or chemical means, such as microprojectile bombardment, chemical methods, or electroporation.

Generational terminology F1: progeny of a cross between two different genotypes; R0 or T0: regenerated transgenic plant (hemizygous for the transgene); R1 or T1: selfed progeny of the R0 or T0, respectively, segregates for the transgene in Mendelian fashion. In floral dip transformation, the treated plant is the T0 generation and hemizygous T1 seed are recovered from selfing T0 plants.

Genetically modified, genetically engineered, and transgenic organism or plant Descriptions used to indicate a plant that has been stably transformed with transgenes from any gene donor, including synthetic genes in any combination that are stably integrated in the nuclear genome.

Intragenics Transformation using only sexually compatible species for the gene and element donor sources but not in the native configuration.

Selectable marker A gene that when expressed by the transgenic cell confers a positive selective advantage enabling the transgenic cell to survive and divide in the presence of a selective agent while multiplication of nontransgenic cells or plant populations is inhibited.

Totipotency The property of regenerating an entire organism from a cell or part of the organism. Regeneration of plants from a transgenic cell via tissue culture enables production of transgenic plants capable of transmitting the transgene to its sexual or asexual progeny.

Transformation Delivery of DNA into an organism for either transient expression of genes encoded by the delivered DNA or for stable integration into the nuclear, plastid, or mitochondrial genomes resulting in germline transmission to progeny or stable expression in asexual propagules.

Vector Assemblage of a transgene including the gene of interest and requisite expression elements along with other genes like the selectable marker and sequences required for DNA transfer and, when applicable, genomic integration.

Introduction

Transformation expands the gene pool for plant genetic manipulation to all organisms and all deoxyribonucleic acid (DNA) sequences. Used as a research tool to investigate gene function, to produce large quantities of valuable proteins and metabolites in plants and plant culture systems, and for crop improvement, plant transformation has become a widely used genetic manipulation tool since its first demonstration in 1983. Theoretically, all plants can be transformed. Practically speaking, transformation technologies have been developed for all major and most minor crop plants and model systems. The earliest successful demonstrations of plant transformation were achieved with tobacco (*Nicotiana tabacum*) and petunia (*Petunia hybrida*) models for plant transformation research at that time because of their well-developed tissue culture properties and high frequency of plant regeneration from those cultures, characterized response to specific selective agents, and susceptibility to *Agrobacterium* enabling DNA delivery (Fraley *et al.*, 1983a,b; Framond *et al.*, 1983; Schell *et al.*, 1983). From that first demonstration of plant transformation in 1983, transformation technologies were rapidly translated to crop plants. The first commercially available genetically engineered food product, the Flavr Savr tomato, was modified for improved shelf life and launched for commercial production in 1994 (Sheehy *et al.*, 1988; Krieger *et al.*, 2008). Although the Flavr Savr product was not a sustained commercial success, it was important from a historical perspective, because it was the first transgenic product to undergo commercial development and regulatory approval setting the stage for commercial launches of the transgenic crops to follow (Redenbaugh *et al.*, 1992). Roundup Ready soybean was then offered for commercial production in 1996 (Padgette *et al.*, 1995) and, along with later developments in other crops, initiated the widespread production of transgenic crops. Advancing from first demonstration in a model system to commercial production in a range of major crops in only 13 years is an astounding pace of technical achievement followed by commercial development. Because transgenic traits provide significant improvements in weed and insect pest control, the adoption rate of crops with transgenic traits by growers has also occurred at a remarkable pace most likely exceeding the rate of adoption of any other crop improvement advancement in the history of agriculture (Brookes and Barfoot, 2013; **Figure 1**). Furthermore, the significant impact of plant transformation on crop productivity is demonstrated by the fact that in 2011 72% of soy, 56% of cotton, 28% of corn, and 23% of canola acreages worldwide were sown to transgenic

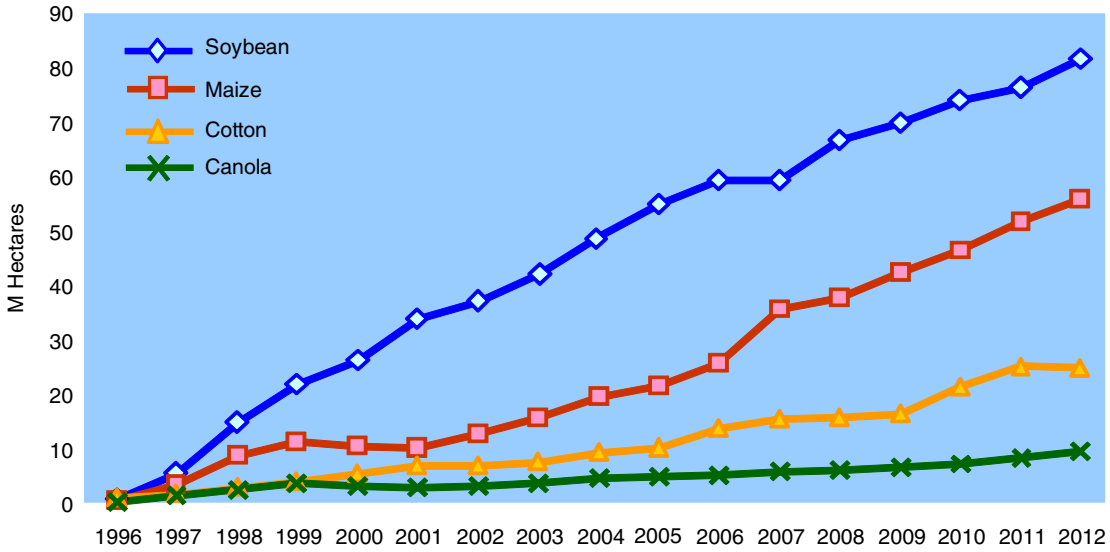

Figure 1 Global area of biotech crops, 1996–2012: By crop (million ha). Reproduced with permission from James, C. ISAAA.org, ISAAA Brief 46-2013.

crops only 30 years after the technology was first invented (Brookes and Barfoot, 2013). Accordingly, the seminal work demonstrating plant transformation in 1983 was recognized by the 2013 World Food Prize because of the major impact of transformation on crop improvement.

This article reviews the technical breakthroughs that resulted in the development of transgenic technologies. Genetic manipulation strategies enabled by transformation technologies as they are applied to both plant biology research and crop improvement are described to provide context to understanding the drive behind developing and utilizing these technologies. This article further focuses on methods for stable integration of transgenes into the nuclear genome because it is the main transformation method used for crop improvement applications to date. Finally, the requirements for and development of plant transformation methods and current challenges and likely future directions in improving transformation technologies are discussed. Many aspects of plant transformation technologies have been comprehensively reviewed. Citations in this article include both first and breakthrough reports along with these review articles. Transformation technologies developed for industrial-scale biopharming to produce valuable compounds are reviewed in the article in this volume by Ursin *et al.*

Genetic Manipulations Using Stable Transformation

Most eukaryotic somatic cell types randomly integrate any sequence of delivered exogenous DNA into the nuclear genome via double-strand break repair mechanism(s) at substantially greater frequencies than by homologous recombination or any other site-directed mechanism(s) (Windels *et al.*, 2003; Somers and Makeravitch, 2004; Tinland, 1996; Salomon and Puchta, 1998; Van Attikum *et al.*, 2001; Mayerhofer *et al.*, 1991; Puchta and Fauser, 2013). Following random integration of the transgene into the nuclear genome, the transformed cell will be hemizygous for the integrated transgene and, as long as it does not have a deleterious impact on cellular processes, the transgene will be transmitted through mitotic division to yield a transgenic cell line (**Figures 2** and **3**). Transformation via random integration is primarily used to add transgene(s) to the nuclear genome and the resultant transgenic plants exhibit dominantly inherited gain-of-function transgenic traits. The importance of this straightforward genetic manipulation approach in research and its significance to crop improvement cannot be overstated as demonstrated in **Figure 1**. Distinctions among the different transformation strategies defined in the glossary have a direct impact on the range of genetic manipulations they enable. From the perspective of the gene pool concept, transgenesis expands the gene pool for crop improvement applications to all DNA sequences. Intragenesis restricts the DNA donor source to relatives in the gene pool of a crop but enables new combinations of elements in the 'intragene,' whereas cisgenics primarily enable allele and cisgene stacking applications. See **Figure 4** for examples of transgene cassettes.

A transgenic strategy to suppress expression of an endogenous gene in the transgenic plant employing *trans*-acting suppression from randomly integrated transgenes was discovered early in the development of transformation technologies. Intentionally structuring the transgene cassette to express the antisense transcript of an endogenous gene in the recipient dominantly suppresses expression of the endogenous gene (**Figure 4(b)**). This 'antisense' strategy has been applied to a range of crop improvements and to impart virus resistance when the antisense sequence is taken from the viral genome. The first example of a commercialized antisense product was the Flavr Savr tomato (Sheehy *et al.*, 1988). The article by Krieger *et al.* (2008) addressed the mechanism underlying this example of antisense RNA technology.

For research applications, random transgene integration throughout the genome enables gene discovery opportunities similar to the uses of transposable element systems but

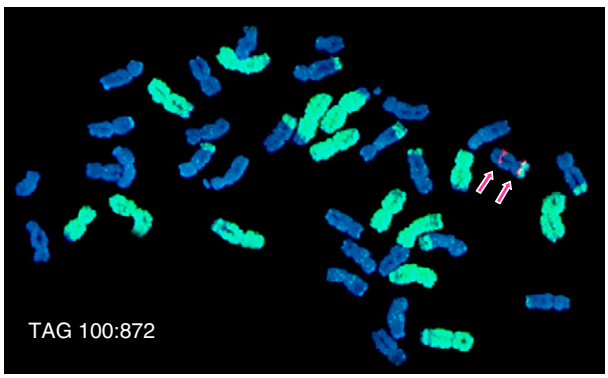

Figure 3 Chromosomes of an oat plant transformed using microprojectile bombardment that is hemizygous for two transgenic loci detected by fluorescent *in situ* hybridization (red and arrows). Oat is allohexaploid containing A, C (green probe for a C genome-specific repeat), and D genomes. Reproduced with permission from Svitashev, S., Ananiev, E., Pawlowski, W.P., Somers, D.A., 2000. Association of transgene integration sites with chromosome rearrangements in hexaploid oat. Theoretical and Applied Genetics 100, 872–880.

with the added advantage that, unlike an endogenous transposase, transgene insertion is not confined to a specific species. Using transgene integration either to knock out endogenous genes via insertion and deletion or to tag or trap endogenous expression elements by integration of cassettes designed to create transcriptional or translational fusions and trap a genetic element of interest has proven extremely useful in plant biology research. For example, transformation populations of *Arabidopsis* have been developed in which nearly every gene in the genome has been disrupted or tagged with a transfer DNA (T-DNA) (Alonso *et al.*, 2003; Kim *et al.*, 2003; Sawasaki *et al.*, 1999). In other examples, promoter tagging via insertional fusion has been used to identify useful expression elements. Detailed characterizations of large populations of T-DNA insertions indicate that a higher proportion of insertions occur in or near genic regions; whether this is because these regions are more accessible to integration because they are euchromatic, more active in double-strand break repair, or simply that selection of transgenic cells requires active transcription of the selectable marker gene is a subject that continues to be investigated. Fewer insertion events produced via direct DNA

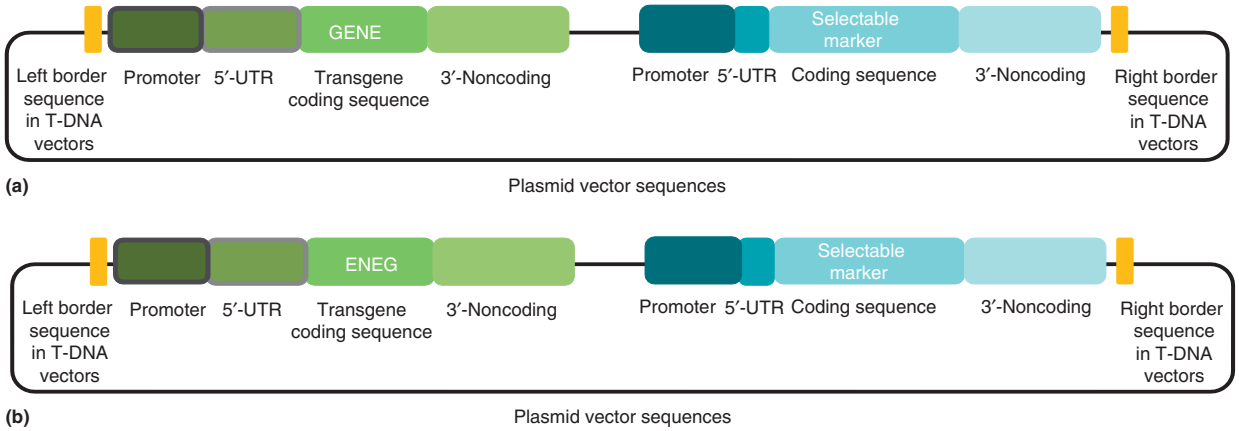

Figure 4 Examples of plant transformation cassettes showing coding and noncoding elements in untranslated regions (UTRs) necessary for expression of the transgene of interest. Selectable marker cassettes are often included on the same delivered DNA. In 2 T marker-free transformations the selectable marker cassette is introduced on a separate T-DNA. The primary difference with direct DNA delivery vectors is the T-DNA borders that are sequences that delineate the T-DNA for transfer from *Agrobacterium* into the plant cell. They have no role on T-DNA integration. (a) A standard format for a gain-of-function transgenic trait that enables positive selection for presence of the transgene. The vector shown is a T-DNA vector because of the presence of the T-DNA border sequences. For the direct DNA delivery, the T-DNA borders are usually not included. (b) The transgene is an antisense configuration of an endogenous gene for transacting suppression. Modified from Kjemtrup, S., Talarico, T.L., Ursin, V., 2014. Biotechnology: Pharming.

delivery have been characterized at this level, but the results suggest that transgene integration follows the same general rules as T-DNA insertion with the possible exceptions that there is less tendency for insertion into genic regions and a higher frequency of multiple transgene sequences (including small fragments) are integrated in multiple loci throughout the genome within a transgenic event (Windels *et al.*, 2001; Svitashev *et al.*, 2000; Makarevitch *et al.*, 2003).

Early in the development of plant transformation systems, it was observed that transgene expression levels are highly variable among transgenic plants transformed with the same transgene using conventional methods for random genomic integration (Horsch *et al.*, 1985). Most frequently this observation is attributed to the molecular structure of the transgene integration locus, the copy number of the transgenic inserts in the same or multiple transgene loci, and the effects of the position in the nuclear genome into which the transgene is integrated. In some transgenic plants, transgene expression can be lost over generations or lead to segregation distortion of the transgenic phenotype even though the transgene is inherited in Mendelian fashion. This phenomenon is referred to as transgene silencing and is triggered by structural duplications in the delivered DNA, rearrangements of the transgene integration locus, the genomic position and context of the transgene locus, by high levels of transgene expression, and likely factors that remain to be discovered. Eukaryotic gene silencing mechanisms were in part elucidated by observations of unexpected transgene expression patterns in plants resulting in an entirely new understanding of eukaryotic gene regulation. For more information on transgene silencing see reviews (Beclin *et al.*, 2002; Depicker *et al.*, 2007).

Plants containing only single copy, unrearranged transgene loci produced with the same transgene often exhibit substantial variation in transgene expression indicating that the position effect of transgene integration is an important variable in determining transgene expression potential. The current paradigm is to compensate for 'position effect variation' in transgene expression by producing multiple plants from a single transgene construct to identify those that exhibit the desired expression profile. Intuitively, site-directed integration is expected to reduce or eliminate position effect variation in transgene expression and preliminary reports support this expectation (Day *et al.*, 2002; Srivastava and Ow, 2001). However, establishing the extent to which this variation is reduced via site-directed integration will require the production and characterization of large numbers of transgenic events with transgenes targeted to individual specified genomic locations to determine whether variation in transgene expression is reduced among the genotypically identical events produced at the same locus and if all or some of the different genomic integration sites exhibit this behavior.

Targeting transgene integration to specific genomic locations or sequences to enable gene replacement and other sequence-specific manipulations has been the focus of intense research since the first demonstrations of transformation. First demonstrated in plants by Paszkowki *et al.* (1988), the frequency of transgenic plants resulting from site-directed integration was too low to be broadly applied to crop improvement (Terada *et al.*, 2002). Recent advances in site-directed genomic cutting strategies have shown that transgenes can be integrated via homologous recombination at improved frequencies bringing this transgenic approach into a useable range (Wood *et al.*, 2011; Li *et al.*, 2011; Zhang *et al.*, 2005; Frauser *et al.*, 2012). As site-directed integration and other genetic manipulations become routine enabling a shift in the transgene integration paradigm from random integration to sequence-specific integration, the range of genetic manipulations will be increased to include endogenous gene knockouts (recessive), directing transgene or allele stacking to specific genomic locations, and allelic or genomic editing (D'Halluin *et al.*, 2008; Ainley *et al.*, 2013; Curtin *et al.*, 2012). The demonstrations of site-directed integration reported to date

indicate that some frequency of R0 plants biallelic or homozygous for the transgene provide a further useful feature (D'Halluin *et al.*, 2013; Shukla *et al.*, 2009; Townsend *et al.*, 2009). Whether crops modified using endogenous gene knockouts or allelic editing will be considered transgenic remains to be determined.

Plastid transformation has been achieved in plants via homologous recombination of the introduced transgene DNA into the plastid genome enabling both gain of function manipulations and gene replacement. In plastid transformation, once the multiple genomes in a plastid and all plastids in the cells of a recipient are uniformly transgenic (called the homoplasmic state), transgene inheritance follows cytoplasmic inheritance (Maliga, 2004). Although very high levels of transgene expression have been observed as a result of plastid transformation, there are no examples of crop plants in production transformed via plastid transformation. To date there are no reported examples of mitochondrial transformation in plants.

Technical Framework for Transformation – Required Components

Conventional plant transformation requires only three components: (1) delivery of DNA into totipotent cells, (2) a means of selection or identification of the transgenic cell, cell culture, or regenerated plant, and (3) cells that are totipotent (**Figure 2**; Gasser and Fraley, 1992). This framework is based on the natural tendency for delivered DNA to be integrated into the nuclear genome via cellular processes resulting in a hemizygous transgenic cell. Plant regeneration from a totipotent transgenic hemizygous cell results in a uniformly transgenic organism enabling stable germline transmission of the transgene to the progeny in Mendelian fashion. From the beginning of plant transformation research, it was recognized that a far simpler route to producing a transgenic plant would be to deliver the transgene DNA into a gamete or gamete progenitor cell followed by pollination to produce a transgenic seed. To date, this method is only widely enabled in the model plant *Arabidopsis* (Bechtold *et al.*, 1993; Chang *et al.*, 1994; Clough and Bent, 1998; Bent, 2000) and to a lesser extent in its close relative canola (Wang *et al.*, 2003). Thus, the great majority of extant crop transformation systems follow the conventional framework, the development of which is examined in more detail from a historical perspective.

The sequence and structure of the DNA molecules themselves are critical for transformation success and for the desired transgene expression pattern for the trait of interest (Komori *et al.*, 2007, 2011). Direct DNA delivery transformation cassettes require only plant expression elements for appropriate tissue-specific and developmental expression of the transgene (**Figure 4(a)**). In addition to the transgene(s) of interest, plant transformation cassettes often contain a selectable marker gene. T-DNA-specific left and right border sequences shown in **Figure 4(a)** are utilized for mobilization of the T-DNA from *Agrobacterium* to the plant cell. No specific transgene cassette sequences are required to guide genomic integration for random integration via double-strand break repair. Site-directed integration requires homologous genomic sequences as substrates for recombination; however, prescriptions of homologous sequence length and nucleotide composition for optimizing site-directed integration frequency and fidelity remain to be determined.

Early transformation work was accelerated by the development of molecular detection methods and establishment of a simple set of basic criteria or proofs that together constituted convincing evidence that a transgenic plant was produced. To demonstrate stable transformation, this proof is simply the detection of the transgene integrated into the genome of the regenerated plant and its transmission following disomic Mendelian inheritance to sexual progeny or stable transmission in asexually propagated crops, i.e., demonstration of the transgenic genotype. Developed by consensus of the scientific community and later articulated in the scientific literature (Potrykus, 1990a,b) as new transformation technologies were developed and reported, these criteria set the bar for proof of transformation and the types of and ways that genetic and molecule assays should be conducted accelerating the development of new transformation technologies. From the current perspective of being able to simply order the synthesis of transgene cassettes from molecular services companies and detect transgenes via whole genome sequencing with the prospects of this approach becoming economically feasible (Kovalic *et al.*, 2012), it is difficult indeed to appreciate the challenges faced by early transformation scientists in demonstrating progress toward developing plant transformation methods. In the 1970s, molecular assay techniques that could be used to prove that a plant was transformed were under development, as were selectable marker and reporter genes that would ease the detection of transgenics. Since that time, plant transformers have rapidly adopted and, in some cases developed, the molecular toolkit for producing and characterizing transgenic plants.

Technical Framework for Transformation – Enabling Breakthroughs

Plant Cell Totipotency – The Regeneration of Whole Plants from Cells

Both animal and plant cells exhibit totipotency. However, in the decades leading up to the first breakthroughs in plant transformation, only plant cell totipotency had been demonstrated and at that time cell and tissue culture methods for regenerating whole plants were developed in only a limited number of species. Breakthroughs in defining tissue culture media and methods during the 1950–80s (Murashige and Skoog, 1962; Eriksson, 1965; Gamborg *et al.*, 1968; Nitsch and Nitsch, 1969; Schenk and Hildebrandt, 1972; Kao and Michayluk, 1975; Chu *et al.*, 1975; Lloyd and McCown, 1980) provided the scientific foundation for the developing field of plant cell and tissue culture (Gamborg and Phillips, 1995; Hall, 1999; Singh and Kumar, 2009). Driven by the demonstrated and potential usefulness of plant cell and tissue culture for diverse applications, including plant propagation, chromosome manipulations like doubled haploid production from microspore culture, mutant selection and as a source of totipotent target cells for transformation, methods for tissue culture establishment and plant regeneration were

rapidly translated to a wide range of plant species during the 1970–80s. By culturing on a defined media containing the requisite balance of phytohormones, a somatic cell in a plant tissue or a gametic cell is dedifferentiated to a state in which its development is rerouted to form a regenerable structure. For example, developmentally fated cells in the scutellum of immature embryos of corn and many other monocotyledonous plants can respond to tissue culture media to form regenerable structures (Green and Phillips, 1975). The fundamental key for the development of a transformation system is that at some stage in the tissue culture-induced processes of dedifferentiation and redifferentiation, a single cell that can be transformed gives rise to the regenerable structure. This generality is supported by the observation that the great majority of regenerated transgenic plants characterized to date are comprised of a single transgenic insertion and not a population of multiple transgenic events.

Plant cell and tissue culture processes commonly involve isolating a defined organ or cell type, often referred to as the 'explant,' and culturing it in media containing phytohormones to begin the dedifferention stage most often referred to as 'callus.' Explants can be as simple as leaf or stem sections of a plant or more specific structures, such as the immature embryo of corn or the cotyledonary node of soybean. In some plants, single cells can be isolated as protoplasts by using hydrolytic enzymes to digest away cell wall material leaving a plant cell bounded by only its cell membrane as first demonstrated by Cocking (1960). Protoplast cultures were initially recognized to be an attractive avenue for plant transformation because of the ease of DNA delivery due to the removal of the cell wall and the single cell nature of the culture simplifying the selection stage of the transformation process. In tobacco and related species, for example, protoplasts can be isolated directly from leaf tissue and cultured to form plant-regenerating (regenerable) callus (Nagata and Takebe, 1970; Frearson *et al.*, 1973; Nagy and Maliga, 1976). In most cases of plant cell and tissue cultures, as in bacteriological culture practices, plant explants can be cultured in liquid or solidified media and because sucrose or other sugars must be supplied in the media, the entire process including explant preparation must be kept axenic, usually involving both sterile technique and inclusion of antibiotics. Callus cells can also be cultured in liquid media to form suspension cultures of various levels of dedifferentiation. Some suspension cultures can be used for protoplast isolation; others are useful cellular targets for DNA delivery. Explant response to tissue culture to form a regenerable culture is dependent on the plant species and its genotype, the explant chosen and its developmental stage, culture media nutrient and phytohormone composition, and the culture environment including temperature, light regime, and humidity control.

Regeneration of whole plants from cells occurs via two different developmental pathways (Duncan, 2011; Vasil, 2008). In somatic embryogenesis, cell divisions result in the formation of an embryoid with a developed root and shoot meristem that can germinate and elongate following a very similar developmental path as a zygotic embryo. In organogenic regeneration, cell divisions result in the formation of an apical meristem-like structure that in a subsequent culture steps forms a root to give rise to the whole plant. Transformation has been achieved using both routes of plant regeneration indicating that as long as the regenerable structures originate from single cells into which DNA can be delivered, the developmental path is of lesser importance. However, in many plant species, regeneration is enabled only via a single developmental path, and in some cases the tissue culture response and plant regeneration capacity is modulated by genotype such that not all cultivars within a species respond to the same degree (Parrott *et al.*, 1989). For this section, it is important to recognize that the limitations imposed by the genotype effect stimulated extensive research in developing tissue culture and plant regeneration protocols that are more genotype flexible via targeting totipotent cells that undergo less dedifferentiation and for shorter periods before regeneration (Birch, 1997). Excellent examples of this approach include targeting cells in the meristem regions of legumes to directly regenerate a transformed shoot (Somers *et al.*, 2003; Ye *et al.*, 2008). The genotype dependence of plant regeneration and impact on transformation and eventual transgenic crop improvement are discussed in more detail in the Section Technical Limitations, Potential Solutions, and Future Transgenic Technology Directions.

A more attractive approach mentioned earlier is to bypass cell and tissue culture steps altogether by targeting gamete or gamete progenitor as in the widely used *Arabidopsis* floral dip method (Clough and Bent, 1998). In this method, plants at a specific developmental stage are inoculated with *Agrobacterium tumefaciens* carrying the gene of interest along with a selectable marker and allowed to self-pollinate and set seed to produce transgenic progeny. The mechanism(s) involved in this method have been characterized. As predicted from the above discussion on the single cell nature of cell and tissue culture-based transformation systems, in the *Arabidopsis* floral dip method a low percentage of the progeny of the treated plant are transgenic because only a few of the numerous gamete progenitor cells are transformed per plant during treatment (Clough and Bent, 1998). Some have postulated that the simplest transformation process would be to treat seed for DNA delivery followed by germination of a transgenic plant. Because mature seed of most plants are completely differentiated structures and have multiple cells that will give rise to the germline, the expected outcome would parallel the *Arabidopsis* floral dip observations in that only a few progeny resulting from the treated seed would be transgenic, most probably hemizygous T1 plants as opposed to the regeneration of a hemizygous T0 plant. Although numerous examples of this method have been reported over the years, only a few have demonstrated stable Mendelian transmission in the generations following the transformation treatment, thus meeting the criteria for demonstrating successful transformation described above. However, there is no doubt that continued research in this area will eventually lead to robust transformation systems that do not require cell and tissue culture.

Transgene DNA Delivery

Direct DNA Delivery

Discovering methods to deliver DNA into plant cells was a key enablement for transformation (Darbani *et al.*, 2008;

Nandakumar *et al.*, 2011). Many developments in plant DNA delivery technologies were built on progress in transformation of microbes and animal cell cultures. Because the plant cell wall is a significant barrier to the delivery of DNA and other biomolecules into the cell, strategies developed for mammalian cell transformation could not be directly applied to plant cells. Two general strategies evolved for delivering DNA into plant cells: direct DNA delivery and *Agrobacterium*-mediated T-DNA delivery. Two major technical breakthroughs in DNA delivery occurred in the late 1980s and early 1990s that enabled rapid expansion in the development of transformation methods to most crops. These were the development of cell wall penetrating DNA delivery methods and the demonstration that *Agrobacterium*-mediated T-DNA delivery occurred across plant taxa, including monocots opening up the range of crops that could be transformed by this method. A historical account of the development to these technologies is useful because it demonstrates how technology development progresses in a highly competitive area of science involving both stepwise incremental improvements and paradigm shifting breakthroughs and the interdependence of codeveloping the transformation framework. In this section, the interdependency is most strongly evident between the DNA delivery method and the cell culture potential of the target species. For historical context, the main conventional wisdom that drove DNA delivery technology option selection during the early 1980s was that *Agrobacterium*-mediated T-DNA delivery was unlikely to work well for transformation of monocot species. Thus, researchers interested in genetic manipulations of these species mostly focused on direct DNA delivery methods in the early years of plant transformation research.

Direct DNA delivery strategies were developed that either removed the cell wall to form protoplasts followed by delivering DNA across the plasma membrane or simply penetrated the cell wall to deliver DNA. Before cell wall penetrating methods were developed in the mid-1980s, translating methods from other systems was the most logical approach. Because protoplasts are structurally similar to mammalian cells, direct DNA delivery into protoplasts was intensely researched employing chemical methods, lipofection, microinjection, or electroporation for DNA uptake, resulting in high rates of transformation in some model systems (Paszkowski *et al.*, 1984; Shillito *et al.*, 1985). These demonstrations of protoplast transformation, in turn, spurred research to develop protoplast culture methods for crop species, especially the monocot crops, because at that time it appeared to be the only avenue for transforming these crops, i.e., methods for cell wall penetration had not been developed. Translation of some of these methods, such as microinjection and electroporation to whole cells, was successful, but these methods were not widely adopted. These early efforts with protoplast transformation were widely applied to plant species amenable to protoplast culture primarily in the Solanacea family. In retrospect, it is surprising that these methods did not produce the first transgenic plants. As indicated, regeneration of plants from tobacco protoplasts was first reported in 1971, providing substantial lead time for the development of DNA delivery methods and selection systems. The first plants produced via direct DNA delivery were reported by Paszkowski *et al.* (1984) and fueled an intense focus on protoplast culture research. As it turned out the extension of these methods to both dicot and monocot species, including corn, was only partially successful and these methods were not able to be widely applied because of the technical difficulty of establishing either direct protoplast cultures or suspension cultures that could produce protoplasts to regenerate fertile plants. The factors influencing plant cell and tissue culture success described in the Section Plant Cell Totipotency – The Regeneration of Whole Plants from Cells were not able to be overcome for these crops to enable development of protoplast-based transformation systems. As in the development of most technologies, the DNA delivery paradigm shifted rapidly with the invention of a cell wall-penetrating method of DNA delivery into plant cells causing most plant transformation researchers to prioritize this method over protoplast-based transformation methods.

As the axiom states "necessity is the mother of innovation" and based on the difficulties with developing regenerable protoplast cultures from the major crops along with the contemporaneous development of excellent cell and tissue culture regeneration for these crops and the still prevailing belief that *Agrobacterium*-mediated T-DNA delivery was not enabled in the monocots, the need to deliver DNA across the cell wall became increasingly clear, stimulating the conception of the simple strategy of 'shooting the DNA into the cell' by John Sanford and colleagues (Klein *et al.*, 1987). Referred to as the 'gene gun,' 'biolistics,' and 'microprojectile bombardment,' this retrospectively elegant innovation of accelerating dense gold or tungsten microparticles coated with DNA so that they penetrate the cell wall to deliver the DNA and the demonstration that the delivered DNA could be expressed by the recipient cells changed the focus of the transformation community from protoplasts as target cells for transformation to plant cells in culture and in intact explants dramatically expanding the options for developing transformation systems in a range of species. This first demonstration of DNA delivery via cell wall penetration initially using a gunpowder charge (Klein *et al.*, 1987) and later pressurized helium (Lowe *et al.*, 2009) along with an apparently simultaneous invention using electrical discharge (Lowe *et al.*, 2009) as the motive forces, followed by the development of the particle inflow technology (Finer *et al.*, 1992), stimulated researchers to apply this technology to transform plants. Within only a year of the publication describing DNA delivery into cells, the first demonstration of transformed model plants was published (Klein *et al.*, 1988a,b). Very soon thereafter were published the first reports of transformed corn and soybeans (Fromm *et al.*, 1990; Gordon-Kamm *et al.*, 1990; Walters *et al.*, 1992; McCabe *et al.*, 1988). To date, microprojectile bombardment remains the predominant direct DNA delivery method, even in light of somewhat simpler methods involving delivering DNA across the plant cell wall using nanoparticles and materials, such as silicon carbide fibers that penetrate the cell wall (Kaeppler *et al.*, 1990; Frame *et al.*, 1994). Surely, continued innovation in developing methods for direct DNA delivery will lead to new and even simpler procedures.

Direct DNA delivery transfers DNA into cells in any form, such as large chromosomal fragments, whole plasmids, or specific sequences either as a single- or double-stranded DNA molecules providing experimental flexibility in preparing the DNA to be introduced. However, because integration of the

delivered DNA into the genome occurs via double-strand break repair mechanisms and the process of DNA delivery can result in DNA breakage, resultant transgenes have been shown to occur randomly integrated throughout the genome, often in multiple copies, truncated, and rearranged, and to contain unwanted but introduced sequences. Evidence has been reported that introducing only the intended DNA sequences via direct DNA delivery will result in a higher percentage of transgene loci that do not exhibit these rearrangements (Fu *et al.*, 2000). Nevertheless, the difficulty and cost of producing sufficient amounts of an isolated DNA sequence for microprojectile bombardment or any other direct DNA delivery system along with the increased frequencies of rearrangements of the integrated transgene that drives up the numbers of transgenic plants required for recovering a plant with the molecular quality desired for commercialization has tended to sway the transformation community away from the widespread use of direct DNA delivery method, especially for production of commercial transgenic crop plants.

T-DNA Delivery

Agrobacterium-mediated T-DNA delivery was the method used to produce the first transgenic plants in 1983 (Fraley *et al.*, 1983a,b; Framond *et al.*, 1983; Schell *et al.*, 1983) and has been further developed to be the main plant transformation method in use today across crops. *Agrobacterium tumefaciens*, the causal organism in the crown gall disease, was recognized in the 1970s as potentially useful for plant transformation because it transfers genes encoded in the T-DNA from its tumor inducing (Ti) plasmid via a type IV secretion system into plant cells to cause the disease (Chilton *et al.*, 1977). The T-DNA carrying the causal genes of crown gall disease are delineated by left and right border sequences (lb and rb in **Figure 1**) that are recognized by the cellular machinery as cleavage sites for T-DNA mobilization (Gelvin, 2000, 2003; Tzfira and Citovsky, 2006; Wang, 2006). Characterization of this system resulted in the demonstration that deletion of the crown gall genes in the T-DNA followed by replacement with transgenes within right and left T-DNA borders enabled the transfer and genomic integration of the transgenes into plant cells. Further development of this system has enabled a series of the so-called binary plasmids that can be amplified in both *Escherichia coli* and *A. tumefaciens* enabling simplified vector construction in *E. coli* followed by transfection into *A. tumefaciens* (Komori *et al.*, 2007). In short, extensive research on *A. tumefaciens* and related bacteria over the past 40 years has resulted in the development of a simple, efficient DNA delivery system for plant transformation that has shown to be useful for research and crop improvement applications in both dicotyledonous and monocotyledonous plants. The previously mentioned prevailing conventional wisdom that monocots could not be efficiently transformed using *Agrobacterium* was corrected in the early 1990s, with the transformation of first rice and then corn achieved by identifying highly virulent strains for *Agrobacterium* and further enhancing them by modifying their Ti plasmids along with using acetosyringone to induce the T-DNA delivery (Hiei *et al.*, 1994; Ishida *et al.*, 1996). A major advantage of *Agrobacterium*-mediated transformation is that T-DNA integrations exhibit less rearrangement compared with transgene DNA introduced via direct DNA delivery (Somers and Makeravitch, 2004). This is presumably because the T-DNA vectors can be assembled to contain only transgene sequences of interest bounded by the left and right T-DNA border sequences and that most frequently only the T-DNA is delivered. Thus, the bacteria are essentially purifying the DNA sequence that is delivered to the plant genome, reducing the probability of undesirable transgene rearrangements that occur in direct DNA when more than the transgene cassette is introduced via direct DNA delivery, for example, entire plasmids containing the transgene. Although there are no direct comparisons of a large population of transgene loci produced via the two DNA delivery methods in the same species using the same selectable markers, the general simplicity of the current T-DNA-based transformation systems along with the increase in the frequency of nonrearranged transgene loci thereby increasing the efficiency of producing the desired transgenic genotype has resulted in its widespread adoption across crops.

A conventional plant transformation experiment with *Agrobacterium*-mediated T-DNA delivery involves inoculating explants with a culture of *Agrobacterium* carrying a binary vector to deliver the transgene cloned into the T-DNA (Gasser and Fraley, 1992). *Agrobacterium* growth and induction of virulence are important variables and are reviewed in Gelvin (2000). *Agrobacterium* adheres to explant cell walls, and chemical signals that are either produced by the plant due to wounding or added to the inoculation and coculture media induce the T-DNA transfer to the plant cell nucleus. Following inoculation, the explants are coculture for a specific duration to allow completion of the T-DNA transfer and initiation of transformed plant cell division. Following coculture, explants are transferred to media that contain antibiotics to inhibit the growth of the *Agrobacterium*. Selective agents are also added to the media to select cells that carry the selectable marker (**Figure 1**). Despite the added complexity of controlling *Agrobacterium* inoculation and growth during plant transformation, this simple method has been adopted across crops. Numerous aspects of *Agrobacterium*-mediated plant transformation are comprehensively covered in Wang (2006).

From Transient Expression to Transgene Integration – Vector Stacking and Selectable Marker Removal

In both direct DNA delivery and *Agrobacterium*-mediated T-DNA delivery, transient expression of transgenes can be detected shortly after DNA delivery. Transient expression assays are, therefore, routinely used with the appropriate marker and reporter genes to demonstrate and monitor transgene delivery when developing a new transformation system. Usually the transient transgene expression in a recipient explant is quite high, suggesting that DNA delivery has taken place into many cells. As the treated explants progress through culturing, transient transgene expression diminishes until stable transgenic tissue sectors develop. This general observation suggests that only a relatively small proportion of recipient cells that initially received the delivered transgene integrate it into the genome, stably express the integrated transgene, and resume cell division indicating importance of selection to isolate transgenic cell lines.

Transient transgene expression assays have been used to improve DNA delivery into cells and although the correlation between transient expression and stable transformation has not been well established, there are many reports indicating that this is a useful approach. In addition, transient expression per se has proven to be a powerful research tool to investigate gene expression and to characterize plant gene expression elements. In some specialized cases, such as in the production of pharmaceutical proteins in plants, *Agrobacterium*-mediated transient systems have been scaled for industrial production because of efficiency and cost savings compared with stable transformation, indicating that very high levels of DNA delivery and transient transgene expression can be achieved using this approach.

When two transgenes are delivered on the same DNA fragment or T-DNA, most frequently both are integrated into the same locus (Schocher *et al.*, 1986; Depicker *et al.*, 1985). This observation demonstrates the vector stacking strategy of introducing multiple transgenes into an integration locus. Conversely, when two transgenes are introduced either on independent DNA fragments by direct DNA delivery or on different T-DNAs, some portions of the transgene integration loci exhibit cointegration of both transgenes in linked form, whereas other loci integrate each transgene singly into different insertions sites that can be genetically either linked or unlinked (Depicker *et al.*, 1985; De Frammond *et al.*, 1986). Thus, there is the possibility of producing a near equivalent of a vector stack by this method as well. But more importantly and more useful are plants produced with transgene integration loci that contain only a single transgene and are unlinked. This transgene loci configuration enables the segregation of one transgene from another in the progeny of the transgenic plant and is especially useful for the elimination of the selectable marker. For commercial applications, as in the production of an improved crop with a transgenic trait, the production of a transgenic plant with only the transgene of interest and not the selectable marker is desired. This reduces the number of transgenes that must be approved for commercial development and reduces complications of transgene expression due to duplication of expression elements. Thus, a common *Agrobacterium*-mediated T-DNA delivery approach to producing marker-free plants is called two T-DNA transformation, where the transgene of interest is introduced on a separate T-DNA from the selectable marker (McCormac *et al.*, 2001). Transformed (T0) plants with unlinked T-DNAs are identified and marker-free, transgene only T1 progeny are recovered.

Alternative strategies for marker removal utilize the phage recombination systems Cre-lox and Flp-frt that have been modified to function in plants (Dale and Ow, 1991; Srivastava and Ow, 2004; Srivastava *et al.*, 2011). In both cases, the recombinases, for example, Cre and Flp recognize and recombine tandem receptor sequences lox and frt, respectively, flanking the transgene sequence to be removed, such as the selectable marker, essentially looping it out. These systems are generally used as two-component systems in which the recombinase is introduced via sexual hybridization with the transgenic plant carrying the transgene flanked by the recombination target sequences. In addition to selectable marker removal, these systems have been shown to be very useful in orchestrating a range of genetic manipulations of transgene sequences and for controlling gene expression.

Selection of Transgenic Cells, Tissue, or Plants

Building on substantial progress in plant tissue culture selection of mutant cell types and regenerated plants, the path to selection of transgenic cells in plant cell and tissue culture was clear. The founding concept for using positive cellular selection in plants to recover rare genetic events, such as mutations or transgene insertions, was derived from its demonstration by scientists conducting microbial and mammalian cell experiments. It was logical that selecting among millions of cells in culture would enable selection of extremely rare transformed cells followed by inducing totipotency to recover whole plants. Because transformation can add a new trait to the recipient cell, the vast majority of selection systems employ positive selection for cells that express a gain of function. During the 1970s and early 1980s, there was a proliferation of plant tissue culture and protoplast selection work that paved the way for the development of the first selectable markers that were used in plant transformation. In some cases, selection systems already defined in microbial or mammalian cell experiments were modified for plant expression (Fraley *et al.*, 1983a,b), in other genes for resistance to specific biochemical inhibitors were identified in other organisms, and in other plant genes were isolated that conferred a selective advantage for the transgenic cells. Selective agents to which their corresponding selectable markers provide resistance to the transgenic cell in general are inhibitors of metabolic or cellular processes, including antibiotics, herbicides, allosteric inhibitors, etc. and proteins encoded by the selectable marker genes are either not inhibited by or degrade or inactivate the selective agent. Selectable markers and their selective agents have been reviewed comprehensively by Joersbo (2011) and Sundar and Sakthivel (2008). The choice of selectable marker gene and selective agent application have been observed to have major impacts on transformation efficiency in terms of the number of T0 plants produced and the proportion of putative transgenic plants that are actually transgenic versus nontrangenic events that escaped selection (escape rate).

Resistance to the selective agent whether in tissue culture or regenerated plants by itself is indicative but not regarded as definitive evidence that transformation has taken place. Nontransgenic escapes often survive selection and regenerate plants. Several reasons have been suggested for this observation, ranging from cellular transport of nutrients from resistant cells to susceptible cells allowing survival to simple tissue-specific differences to the selective agent. Because of these phenomena, additional evidence, including molecular detection of the selectable marker gene or gene product, and/or the detection of the phenotype of an additional transgene are required. Accordingly, reporter, screenable, or visible markers that are extremely useful research tools to understand molecular mechanisms, including gene expression, have also been important in developing new transformation systems. Two widely used systems that require a substrate to produce a detectable product in transgenic cells and tissues are the enzymes *E. coli* B-glucuronidase (*gusA*) (Jefferson *et al.*, 1986)

and firefly luciferase (*luc*) (Ow *et al.*, 1986). Another marker green fluorescent protein (*gfp*) (Chalfie *et al.*, 1994) fluoresces when exposed to the appropriate wavelength. Of these, *gusA* and *gfp* have played major roles in transformation system development. These reporter genes are often used to track transgenic cell lineages in cell and tissue culture selection or to provide stronger evidence of transformation through the observation of reporter gene expression, in addition to resistance to the selective agent. Using a reporter gene to select transgenic plants has also been reported with some success (Kaeppler *et al.*, 2002) but has not been widely adopted most likely because of the extra labor associated with detecting relatively rare transformation events.

Transgenic plants have also been produced by simply conducting molecular screening of regenerated plants without any selection. Theoretically most useful when transformation frequencies are very high, this was first demonstrated by Shillito *et al.* (1985) when transgenic tissue cultures recovered from direct DNA delivery into protoplasts were detected by PCR analysis at a remarkably high frequency of 2% of cultures screened. Although demonstrated in other systems, the cost, time, and labor needed to sample and assay large numbers of plants have deterred wider adoption of this approach. For example, to identify transgenic plants, Shillito *et al.* (1985) required a 50-fold increase in molecular assays compared with employing a tight selection system to recover a 2% transformation frequency. However, future advances in molecular assays could reduce the cost of this differential, making this approach feasible.

Technical Limitations, Potential Solutions, and Future Transgenic Technology Directions

The ideal transformation system for crop improvement should be (1) rapid, simple, and inexpensive; (2) genotype flexible; and (3) efficient in that a high proportion of the transgenic plants produced are useable for commercial production, i.e., stably express the transgene(s) and have an intact single insertion of transgene cassette sequences. From the preceding discussion it is clear that some crop and model plant transformation systems are very efficient; however, none fully meet the criteria for an ideal system. Nevertheless, the impressive pace of transformation system development over the last 30 years combined with the large positive economic impact realized through the use of transgenic crops will continue to push crop transformation systems toward these ideals.

To become more rapid, simple, and inexpensive, a transformation system probably should be either automated to reduce labor or not be based on laborious tissue culture steps that must be conducted by specialists or require axenic culture conditions. As mentioned, only the model *Arabidopsis* is routinely transformed without a tissue culture step and that only a few progeny of the treated plant are transgenic and those selected are hemizygous for the transgene. Nevertheless, this is an extremely rapid process that requires only specialized *Agrobacterium* treatment capacity and controlled plant growth conditions that combined with the rapid growth characteristics of *Arabidopsis* with its short seed-to-seed life cycle and prolific seed production add up to an extremely efficient transformation system as seen in the production of libraries comprised of more than 100 000 T-DNA insertion events for gene function studies. However, nontissue culture-based transformation methods like floral dip or even seed transformation, if they became routine, may save labor and eliminate the need for specialized axenic propagation facilities but may not actually be as rapid as the extant systems when viewed from the genetic manipulation perspective. If, for example, soy could be transformed by the floral dip method like *Arabidopsis*, a transgenic homozygote would be recovered in the T2 progeny, whereas when soy is transformed using the cotyledonary node method, homozygotes are recovered in the T1 progeny produced by the T0 plant regenerated from tissue culture. Thus, the in planta method will most likely add another generation to produce transgenic homozygotes, even though the transformation treatment itself is apparently faster and simpler than the tissue culture methods. There is significant research activity in developing whole plant transformation systems, but all will more likely add another generation to the production of homozygous transgenic plants because of the intrinsic multicellular structure of the germline progenitor that has already been formed in the seed. Even if DNA delivery were so efficient that the majority of cells giving rise to the germline were stably transformed, they would be comprised of different transgenic insertions and the production of homozygous transgenic progeny would still occur in the T2 generation. Nevertheless, there is no doubt that advances in transformation technologies will result in faster and cheaper methods for transforming plants. Three areas emerge from the literature as likely directions. Specifically, tissue culture-based plant transformation systems will continue to be simplified, shortened, automated, increasing throughput and reducing costs. A good example of a simplified system has been developed for some legumes, including soy, in which cells in the apical meristems in germinated seed are targeted for DNA delivery followed by cell selection and plant regeneration. The transgenic cells under selection apparently form a transgenic apical meristem giving rise to a uniformly hemizygous transgenic T0 shoot that is later rooted. Explant isolation in this system has been automated dramatically increasing system throughput and reducing manual labor. In another approach, continued research into targeting seed and gametes or their progenitor cells may result in a breakthrough enabling its routine use in crop plants. Finally, dramatic improvements in site-directed transgene integration could enable integration into the same genomic DNA sequence in all transformed cells, including those in the multicellular germline such that male and female gametes had the same integrated locus producing a T1 homozygote. As mentioned, this site-directed DNA approach could be applied in a tissue culture system and result in the production of homozygous T0 plant, provided that the directed integration system was efficient enough to cause insertion into both homologs resulting in a homozygous transgenic cell rather than a hemizygote.

Genotype flexibility of crop transformation is desirable because it impacts the rate of development of and genotypic diversity of transgenic crop varieties. Conventional transgenic crop improvement begins with the identification of a transgenic plant that efficaciously expresses the transgenic trait and that has a simple, ideally intact, unrearranged transgene locus

inserted precisely into the genome in an acceptable region that does not impact adjacent endogenous genes. Following identification of a commercial quality insertion, the transgene locus is introgressed into breeding lines for variety development. The genetic relationship of the germplasm used to produce the transformed plant to the elite breeding lines is important for two reasons. First, the less related the two lines are, the more the cycles of backcrossing are required to transfer the transgene and recover the elite parent genotype. Second, the predictive value of transgenic trait efficacy in the transformation germplasm for its performance in the elite germplasm may be reduced. Thus, being able to transform any genotype of a crop or at least the most recent germplasm in a crop improvement program would be ideal because it could accelerate variety development from the transgenic line. In many crops, because of the time required to identify transformable genotypes and to optimize the efficiency of their transformation systems, the genotypes used for transformation have little relationship to the leading germplasm of the breeding program. Of course, the breadth of germplasm diversity within a crop around the globe makes this even more challenging. Thus, over the years there have been several efforts to develop transformation systems for crop plants that are more genotype flexible. Genotype effects on transformation potential are exerted on at least two different steps in the conventional framework, tissue culture regeneration, and DNA delivery. Tissue culture response can be further defined by responses to each stage of culture induction, for example, callus response and plant regeneration therefrom. The factors that effect tissue culture response have been discussed in the Section Plant Cell Totipotency – The Regeneration of Whole Plants from Cells. The effect of these factors varies with species, explant for culture initiation, culture type, and plant regeneration path, for example, somatic embryogenesis versus organogenesis. There has been some work to identify genes controlling the genotype responsiveness in maize and reports of intentionally breeding lines for culture response, but for the most part screening germplasm for its culture response is the main avenue to identifying transformable genotypes. An alternate approach is to develop tissue cultures from explants or with culture types that are less affected by genotype, as in the example using meristem explants for soy as described by Ye *et al.* (2008). It seems that advances along this path and a breakthrough in planta transformation are most likely to break the genotype barrier to transformation. The other genotype effect is in response to the DNA delivery treatment. This effect can be subdivided into at least two main categories – wounding responses and resistance to *Agrobacterium* infection. The response of cells and tissues treated for DNA delivery to wounding during DNA delivery or contact by *Agrobacterium* during inoculation and coculture can adversely affect culture response. Germplasm screening and genetic selection approaches can be applied to identifying responsive genotypes, but great progress has been reported on identifying factors to alleviate these effects, especially in *Agrobacterium*-mediated DNA delivery.

The third strategy to developing the ideal transformation system is to increase the proportion of transgenic plants produced from a single construct that could be advanced to commercial production. This can be achieved by improving the molecular quality of transgene integration loci and selecting transgene locus locations that increase the probability of recovering trait efficacy and stable expression over generations by dovetailing with the breeding strategy to combine transgenic and native traits for that crop. There are a few published examples that document the proportion of R0 events initially produced which meet all quality standards necessary for commercialization, but it usually is in the range of 1% or less. For example, in *Agrobacterium* transformation of soybean only ~20% of plants produced using standard procedures exhibit single copies of the transgene without any other sequences from *Agrobacterium* (Ye *et al.*, 2008). Of these, some portion would be expected to meet the transgene expression level for trait efficacy and stably express the transgene because of previously mentioned genomic position effects on the transgene locus. Then of these, some smaller portion would be in a desired genomic location and do not disrupt an endogenous gene. Ultimately, to produce plants meeting commercial requirements, the majority of transgenic plants initially produced are of no use. Examples in the literature show that molecular strategies can improve the frequency of single-copy transgene loci, but these methods only partly improve the frequency of useful plants, because they have no impact on the genomic location of transgene integration and thereby position effects on transgene expression. Instead, multiple transgenic plants are produced from the same transgene construct and must be evaluated to identify the plants with the desired molecular structure of the transgene locus and appropriate transgene efficacy and expression patterns that meets commercial product performance specifications and that will be introgressed into the breeding germplasm for eventual production as a commercial variety with a transgenic trait. Directing integration of transgenes into specific genomic sequence locations remains the most promising approach to produce quality transgene locus structures in a desired genomic location. As discussed previously in the Section Genetic Manipulations Using Stable Transformation, methods to accomplish this are currently undergoing rapid development and are approaching useful frequencies for applications of site-directed integration. By definition, directly integrating a specified transgene locus into a sequence-specified genomic insertion target, whether by homologous recombination or some manipulation of double-strand break repair, ensures that a single-copy transgene integration locus will be created at the targeted genomic sequence location, reducing the attrition of events due to the random transgene integration that takes place in all extant transformation systems. Theoretically, all plants recovered from directed integration of a transformation cassette will be identical at the level of the transgene locus structure and location eliminating position effects as a source of variation in transgene expression. In addition, some frequency of the T0 transgenic plants may be homozygous for the transgene providing a further advantage of time savings. Thus, fewer transformed plants may need to be produced per transformation cassette to validate transgene efficacy and all plants could meet the commercial quality criteria at the molecular level dramatically increasing the efficiency of transgenic crop improvement.

Future progress along these three paths toward the ideal transformation system is interesting to consider. First, it seems more likely that site-directed integration once developed as a

routine method will be enabled in all plant species, because site-directed integration either overrides or recruits cellular processes common to all higher eukaryotes. In addition, from a historical perspective, DNA delivery appears to be the most genotype-neutral component of extant transformation systems. This seems already to be the case based on recent literature on site-directed integration and it will be interesting to see if this speculation is borne out over the next few years. The effect of genotype on the totipotent explant and plant regeneration route appears to be the major constraint. However, as the understanding of the molecular and genomic basis of plant development continues to grow, it seems more likely that avenues for overriding the genotype effect on cell and tissue culture may become apparent. Furthermore, in keeping with the disruptive 30-year history of plant transformation research, a breakthrough will occur in whole plant- or seed-based transformation that will drive a paradigm shift away from cell and tissue culture-based transformation systems, obviating the challenges they present.

Tree Fruits and Nuts

BS Jacobs and TM DeJong, University of California, Davis, CA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Coefficient of variation (CV) A normalized measure of variation in a dataset. Calculated as the ratio of the standard deviation to the mean.

Handler A business which receives nut crops after harvest, processes them for sale, and packages them for distribution in the retail food industry. Processing typically involves removing hulls, drying nuts, and fumigation to control pests.

Packing house A business which receives fruit after harvest, sorts fruit by size and quality, washes fruit, and packages fruit in crates or flats for distribution within the retail food industry.

Postharvest shelf life The period of time after harvest during which consumption is considered acceptable.

Standard deviation (SD) A measure of variation from the average value of a dataset. Calculated as the square root of the variance of a dataset.

Introduction

California is a center of agricultural production in the US. In 2012, the US produced approximately US$225 billion in agricultural crops, with almost 12% of total domestic production centered in California (all crops except for horticulture, NASS, 2012). Today California tree fruit and nut agriculture is a substantial component of the state's economy. In 2012, California tree fruit and nut production totaled almost US$17 billion (NASS, 2012). California is the primary producer of some of the largest specialty crops produced in the US. For example, almost all domestic almond, olive, pistachio, plum, prune, nectarine, processing peach, apricot, and English walnut are produced in California (NASS, 2012). Additionally, more than one-third of domestic sweet cherry and fresh market peach are grown in California (NASS, 2012).

California agriculture has not always been dominated by tree fruit and nut production. Over the past 30 years agriculture in California has shifted from field crops and livestock to a diverse array of specialty crops. Field crop and livestock production declined from 56% of agricultural sales in 1970 to 20% in 2000. In contrast, fruit and nut tree crops expanded dramatically during the same time period to 28% of agricultural production in 2000 (Johnston and McCalla, 2004).

In this article, the authors explore recent shifts in California industries that have had substantial impacts on farmers and production of tree fruit and nuts. Specifically, the authors highlight the importance of two factors: (1) long-term trends in crop prices and (2) changes in the handler, processor, and food retail industries in determining farm profit margins and competition among farmers. Changes in food industries are important determinants of the availability of research, marketing, opportunities for small farms, and changes in orchard management practices. The authors contend that shifts in California tree fruit and nut production differ between crops produced for fresh market consumption and crops produced for processing or commodity markets. As the largest producer of tree fruit and nut crops in the US, California constitutes a substantial portion of the worldwide market. The effects of fluctuations in crop prices, market demand, and changes in food retail industry on tree fruit and nut agriculture in California are likely to serve as a predictor of patterns that are emerging in other tree fruit and nut growing regions around the world, especially those that operate in free market economies or where there is consolidation of marketing channels. Finally, the authors review what is currently known about potential impacts of climate change on California tree fruit and nut agriculture.

Fresh and Commodity Market Tree Crops in California: Definitions and General Trends

The primary fruit and nut tree crops grown in California can be classified according to the market where they are sold. Tree fruit crops are produced for a wide range of applications including fresh market consumption and processed foods (canning, juice, frozen, and dried products). The stringency of fruit quality standards and postharvest storage life differ substantially between fresh and processing markets. Growers producing tree crops for fresh and processing markets use specialized farming and harvest operations tailored to the requirements of each market. Ninety-three percent of fruit and nut growers in California specialize either in fresh market or processing production because of different quality standards and orchard management practices (Lee and Blank, 2004).

Definition of Fresh Market and Commodity Market Crops

The authors define commodity crops as crops with a long (greater than 6 months) postharvest storage life and crops produced primarily for processing applications. The most common commodity tree crops grown in California are almond, pistachio, walnut, prune, olive, and cling peach. All nut crops, regardless of their end use, are classified as commodity crops because they have long storage lives and are almost all processed (hulled and shelled) before sale. Although a small percentage of prunes are sold for fresh consumption as 'sugar plums' (2–3%, Day and Buchner, 2012), the majority of prunes are dried immediately after harvest and have long storage lives (Thompson and Johnson, 2012). All olives produced in California are used in processed food applications. Forty-nine percent of olive production is used in canning and

46% is crushed for oil (NASS, 2012). All California clingstone peaches are produced for canning and processed food applications (NASS, 2012).

The authors define fresh market crops as crops with at least 70% of the annual production sold for fresh consumption with short (less than 6 months) storage life postharvest. The most common fresh market fruit tree crops grown in California are cherry, kiwifruit, nectarine, freestone peach, pear (except Bartlett), and plum. Although some fresh market fruit crops are used in processing, these industries are dominated by fresh market sales in California. Between 70% and 100% of production (tons) is sold for fresh consumption (Figure 1; NASS, 2012). For example, only 27% of freestone peaches produced in California are sold for drying, freezing, or other processed food applications (NASS, 2012).

Several fruit tree crops grown in California do not fit well into commodity or fresh market categories and merit separate discussion. Apple, apricot, and Bartlett pear grown in California are sold in both fresh market and processing applications, although many aspects of orchard management and production more closely resemble the other 'fresh market' crops. Only 46% of California apple production is sold to fresh market, with the rest sold to processing applications including juice, canning, and other processed foods (NASS, 2012). Similarly, 60% of apricot production is sold to fresh market and 40% is sold for drying, canning, or other processed food applications (NASS, 2012). Approximately 77% of California Bartlett pear production is sold for processed food applications, with only 33% of production sold to fresh market (NASS, 2012). These three crops will be discussed separately and used as a test case to compare and contrast the relative importance of different market pressures in driving tree fruit and nut production trends.

Long-Term Trends in Fresh Market and Commodity Crop Production and Markets

Commodity crop production currently dominates California tree fruit and nut agriculture (Figure 1). Seventy-three percent of the total tree fruits and nuts grown in California can be classified as 'commodity crops,' whereas only 27% are sold to fresh markets (Figure 1). Nut crops comprise 77% of the commodity crop production in California (NASS, 2012). The California fruit and nut tree crop industries have not always been as strongly skewed toward commodity crops. Over the past 30 years commercial nut production has increased dramatically, whereas fresh market fruit production has declined. Between 1982 and 2012 approximately 354 000 additional acres of almond were planted for a statewide total of 790 000 acres in 2012. In that same time period 64 000 new

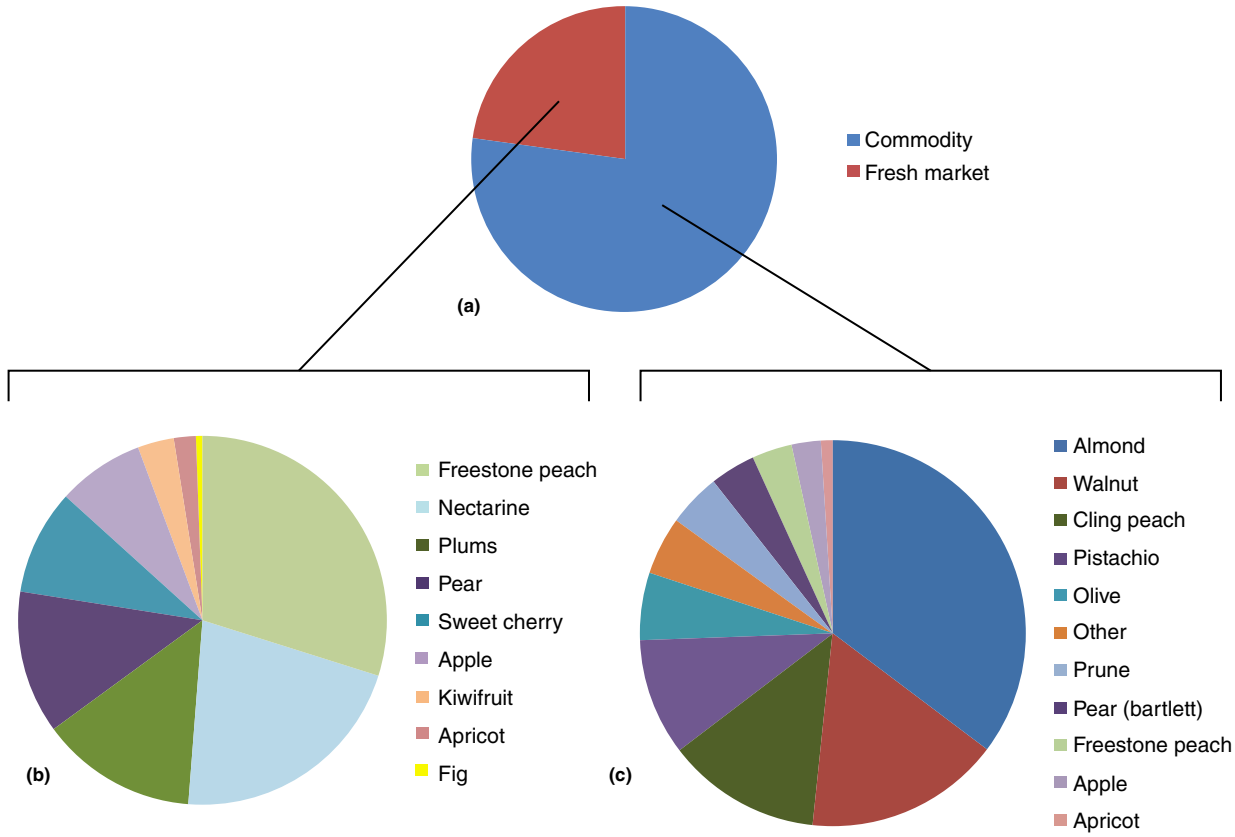

Figure 1 Total California fruit and nut tree crop production for fresh markets (838 060 tons) and commodity (2 842 500 tons) markets in 2012 (a). The distribution of fresh market (b) and commodity (c) production in tons for each major fruit and nut tree crop in 2012. Fresh market tree crop production was dominated by peach, nectarine, and plum in California. Almond, walnut, cling peach, and pistachio made up almost two-thirds of commodity crop production in 2012. Raw data on California fruit and nut production obtained from the National Agricultural Statistics Service (NASS), 2012. USDA National Agricultural Statistics Service Survey and Census Data Query Tool. Available at: http://quickstats.nass.usda.gov/ (accessed 16.04.13).

acres of walnut were planted for a statewide total of 264 000. Pistachio acreage also increased from 34 726 to 178 000 (NASS, 2012). In contrast, the number of acres devoted to peach production dropped by 36%, from 74 000 in 1982 to 47 000 in 2012. Approximately 65% of current California peach production is sold to food processing applications (NASS, 2012).

Long-term shifts in fresh market and commodity crop acreage align with long-term trends in crop value (price per pound). **Table 1** displays the 13-year average (1999–2012) price per pound and standard deviation in price per pound for nut crops (almond, walnut, and pistachio), fresh market crops (plum, freestone peach, and nectarine), and crops sold to both fresh and processing markets (apricot, Bartlett pear, and apple). These data reveal several trends in long-term mean prices for each crop and year-to-year variability in crop value. Fresh market fruit crops have a higher long-term average price per pound than fruit commodity crops. Additionally, fresh market crop prices have standard deviations that are two times greater than fruit crops produced for processing. Year-to-year variability in crop value has important economic consequences for small farms with fewer assets and financial resources available to withstand years when crop values are low (Perez and Ali, 2009). The reduced risk associated with stable crop values in fruit commodity crops may balance out the lower average crop values for small growers.

Increases in nut crop production over the past 30 years in California may be fueled by high average crop values. Nut crop prices have substantially higher long-term averages and standard deviations in crop value than fresh market and commodity fruit crops (**Table 1**). Higher average values result in greater profitability for individual growers, enabling small and medium-sized farms to withstand year-to-year variation in prices. Economic analyses demonstrate that a grower's decision to plant one crop over another in California is dominated by long-term average price per ton, not necessarily variation in value year-to-year or short-term drops or increases in price (McClarty *et al.*, 2007).

Table 1 Summary statistics for California fruit and nut production. The average price per pound and standard deviation were calculated from annual data available from 1997 to 2012. Apricot, Bartlett pear, and apple statistics are shown separately for sales to fresh market and processing markets. All cling peach and prune production was sold to processing markets

Crop	*Average ($ lb^{-1})*	*Standard deviation ($ lb^{-1})*
Fresh market crops		
Plum	0.24	0.06
Freestone peach	0.20	0.04
Nectarine	0.24	0.06
Apricot	0.38	0.16
Pear (exclusive Bartlett)	0.18	0.06
Apple	0.33	0.09
Average	0.26	0.08
Commodity crops		
Almond	1.64	0.54
Pistachio	1.59	0.44
Walnut	0.76	0.27
Average	1.33	0.42
Prune	0.25	0.10
Apricot	0.15	0.03
Bartlett pear	0.14	0.02
Apple	0.09	0.02
Cling peach	0.15	0.02
Average	0.16	0.04

Handling and Marketing of Fresh Market and Commodity Crops

After harvest almost all fruit and nut crops grown in California are sold to a packing house or handler who sorts the crop according to quality standards, markets the crop, and packages it to be sold (Lee and Blank, 2004). Packers and handlers typically sell directly to food retailers or to the food processing industry. Fruit crops that are sold fresh to retailers, and ultimately the consumer, are discussed here as fresh market crops. All nuts and fruit crops sold for processing are discussed here as commodity crops.

During the past 30 years tree crop production shifted from fresh market fruit to commodity crops. At the same time, the retail food industry consolidated into fewer large domestic and international companies (Johnston and McCalla, 2004; Richards and Patterson, 2003). The number and size of packing houses in California available to purchase and sort fresh market produce declined sharply from 278 in 1999 to 143 in 2009 (Linden, 2009). In contrast, the number of packers and processors available for nut crops in California increased. There are 178 unique almond and walnut handlers listed by the California Walnut Board and the Almond Board of California in 2013. The number of packing houses and handlers in each industry determines the number of entities available to purchase crops, the strength of competition among growers, and the importance of external marketing boards in domestic and international marketing.

Marketing and Sales Options for Fresh Market Fruit Crops

There are two primary avenues available to sell and market California fresh market fruit crops. Growers sell produce directly to consumers at local farmers' markets or fruit packing warehouses. Farmers' market sales typically result in a higher profit because produce is sold and marketed by the grower without additional overhead costs (Lee and Blank, 2004). However, the volume of produce sold at farmers' markets is limited and they are generally more appropriate for small farms or specialized crops. Approximately 32% of fresh market pome fruit (apple and pear) and 10% of fresh market stone fruit are sold directly to consumers in California (Lee and Blank, 2004). Outside local farmers' markets the majority of fresh fruit sales are brokered by large packing houses that work directly with domestic and international food retail chains. Forty-two percent of fresh market apple and pear production and 68% of fresh market stone fruit production are sold to independent shippers and brokers (Lee and Blank, 2004).

The majority of fresh market fruit sales in California are controlled by a shrinking number of large packing houses. The number and diversity of destinations to which fresh market crops are sold is also declining, resulting in increased competition among packers for limited access to domestic and international markets. Before the recent consolidation of packing houses, fresh market crop growers had a greater diversity of destinations for their crop and avenues of marketing to consumers and reduced direct competition among growers.

There is substantial competition among fresh market fruit growers and packers in the timing of fruit production due to the limited storage life of fresh market crops, the short season in which they are sold, and the need to harvest and sell fruit to packing houses at a time when they are not overwhelmed with fruit from other growers. For example, fresh market crop growers receive a significant price premium for early season fruit. In 2011, the average price of peaches at the beginning of the season was US$0.65 per pound (May). The price dropped sharply to approximately US$0.32 per pound throughout the rest of the season (ERS, 2011). However, yields of early season fruit cultivars are significantly lower and production costs are higher than later season cultivars. Differences in price do not necessarily reflect profit. It is very difficult to predict the long-term profitability of any cultivar a grower chooses to grow.

Marketing and Sales of Commodity Fruit and Nut Crops

The landscape of commodity crop marketing and sales differs in a few important ways from fresh market crops. The long shelf life of commodity crops facilitates international shipping and sales, resulting in lower competition among individual growers and reduced fluctuation in prices from year-to-year. The most common nut crops grown in California are regularly stored by processors and handlers for up to 1 year postharvest, substantially longer than fresh fruit crops. Fruit commodity crops used in processing have less strict grading and quality standards than fresh market fruit crops and can be stored longer than 6 months after processing. A long storage life ameliorates the need to time sales seasonally and stabilizes fluctuations in prices year-to-year. On average, processed fruit prices are substantially less variable across years than fresh market fruit prices in California. The long-term standard deviation in price per pound of fresh market crops is more than double the standard deviation in price per pound of fruit commodity crops (standard deviation in $/pound, **Table 1**).

Marketing boards are financed by grower or handler fee assessments and serve an important role in marketing specific crops to domestic and international consumers. The primary responsibility of marketing boards is to improve the visibility of a crop and increase consumer demand. In addition to grower and/or handler fee assessments, marketing boards receive funding from the US Department of Agriculture (USDA) Market Access Program to organize and finance promotional activities for US agricultural products. Increased worldwide demand and advertising campaigns funded by marketing boards and the USDA have reduced competition among individual commodity crop growers and handlers for sales to large domestic and/or international retail chains.

The destination of commodity crops grown in California varies among nuts, pome fruit, and stone fruit. The majority of nuts produced for processing applications are sold to marketing cooperatives (51%), with a smaller proportion sold to processors under contract without a predetermined price (33%, Lee and Blank, 2004). In contrast, commodity fruit crops are sold primarily to processors under contract (60% pome fruit and 58% stone fruit), with fewer sales to marketing cooperatives (13% pome fruit and 38% stone fruit, Lee and Blank, 2004).

Opportunities for Small Farms

Untied States agriculture is dominated by small farms. The most recent US agricultural census, in 2007, demonstrated that the majority of tree fruit and nut farms nationwide are small with less than 50 acres and US$40 000 in production value. In 2007, small tree crop farms also dominated the California fruit and nut tree industry. Seventy-four percent of the total fruit and nut tree operations spanned 0.1–50 acres. Of the remaining operations 24% spanned 50–500 acres, and only 2% spanned more than 500 acres (NASS, 2012).

Nationwide, larger farms have generated a greater proportion of total fruit and nut production than small farms. For example, between 2004 and 2006 only 5% of fruit and nut farms in the US were classified as large, but they produced 58% of sales. In that same time period small fruit and nut farms only contributed approximately 5% of total US sales (Perez and Ali, 2009). Although the majority of fruit and nut tree farms in California today are small, the number of small farms has declined steadily from 1998 to 2006. In contrast, the number of medium and large farms increased in the same time period, indicating that the fruit and nut tree industry is in the process of consolidation into larger entities (Perez and Ali, 2009). A close look at changes in the number of fruit and nut farms by size illustrates different trends between commodity and fresh market crop growers from 2002 to 2007. On average the number of small fresh market growers decreased, a pattern consistent with national trends, whereas the number of small commodity crop growers remained constant or increased (**Table 2**).

Trends in California Fruit and Nut Farm Size

Ninety percent of farms (across all crops) in the US are small, and the number of small farms is declining nationwide in favor of fewer large farms (Hoppe *et al.*, 2010; Perez and Ali, 2009). A closer look at the California tree fruit and nut industry distribution by farm size reveals distinct trends in fresh market crops, fruit commodity crops, and nut commodity crops (**Table 2**). Between 2002 and 2007 the number of individual fresh market fruit farms decreased in all categories but one. The only farm size category that increased over this time period was fresh market farms with over 500 acres. A decline in the number of fresh market fruit growers in all but the largest size category is consistent with observed long-term trends in crop value (**Table 1**) that reduce the profitability of fresh market farming in all but the largest, and most efficient, operations. In contrast, the number of very small farms growing fruit and nut commodity crops increased over the same time period, demonstrating the economic viability of

Table 2 Comparisons of the percent change in number of operators by farm size from 2002 to 2007

Crop	*> 500 acres (%)*	*100–500 acres (%)*	*50–100 acres (%)*	*5–50 acres (%)*	*0.1–5 acres (%)*
Fresh market crops					
Freestone peach	83.3	−15.1	−47.5	−35.1	5.8

small commodity crop farms. This distinct trend in commodity crop grower numbers by farm size is consistent with the stable crop values in fruit commodity crops and substantially higher average value of nut crops.

Small Farm Profit Margins

There are several important differences in the economics of small and large fruit and nut tree farms that determine long-term competitiveness and sustainability. Average cash reserves, the difference between costs and income, differ substantially between small and large farms. The profitability of fruit and nut farms increases as the size of the operation increases. Large, specialized fruit and nut farms average US$72–74 in production costs per US$100 earned, whereas small farms run at a consistent deficit of US$113 spent on production costs per year for every US$100 in cash income (Perez and Ali, 2009). The differences in average profitability between small and large fruit and nut farms create significant hardships for small fresh market fruit growers over the long term. Small fresh market farmers are less likely to withstand sharp drops in crop value and increases in operational expenses (manual labor, fertilizers, and fuel) because they have fewer cash reserves available than large farms.

Sources of Risk and Opportunities for Small Farms

The number of packing houses available to purchase and market fresh fruit declined sharply from 1999 to 2009 (Linden, 2009), increasing competition between individual growers. Given the diminished average profits associated with small farms, small and medium fresh fruit farms are out-competed by larger, more efficient farms. McClarty *et al.* (2007) demonstrated that declines in acreage for fresh market stone fruit crops and increases in average farm size in California are associated with declines in long-term average crop value. This association helps explain the rapid transition from fresh market to commodity crops over the past 20 years.

Although the average price per pound for fresh market fruit is greater than fruit commodity crops, fresh market crop values fluctuate more from year-to-year (**Table 1**). Small and medium fresh market growers, with smaller cash reserves (Perez and Ali, 2009), are poorly suited to buffer against price crashes compared to larger growers with larger cash reserves (McClarty *et al.*, 2007).

Two factors can help ameliorate risk associated with small farms: income supplementation from off-farm sources and high average profit margins. In California smaller fruit and nut crop growers have a higher percentage of their total income derived 'off farm' than large farms (Lee and Blank, 2004), creating a financial buffer from price fluctuations and low profitability. The negative effect of exceptionally high variation in nut prices on small farms is ameliorated by a high average price per pound (**Table 1**). Approximately 63% of small fruit and nut tree farms in California specialize in high-value nut crops (NASS, 2012).

Availability of Research and Development Programs

Marketing boards are commonly used to organize an agricultural industry and consolidate funds for marketing, research, and development. Marketing boards are typically funded by an assessment from growers or handlers taken as a percentage of crop sales. Although growers and handlers forfeit a small portion of sales, they benefit from industry-wide consolidation of resources focused on improved marketing and research. Marketing boards use three primary methods to enhance the production and sales of a specific crop: (1) advocating for the interests of that industry to policy makers, (2) running crop-specific domestic and international marketing programs, and (3) funding independent research. California tree fruit and nut agriculture has a long history of marketing boards financed by growers and packers to promote specific fresh market and commodity crops. There are several important differences in the prevalence and longevity of fresh market and commodity crop boards that are linked to broader trends in each industry.

Commodity and fresh market crops have different histories of supporting marketing boards in California as a result of differences in the degree to which each is consolidated around large growers and handlers/packing houses. All of the major commodity crops in California (almond, cling peach, walnut, pistachio, olive, and prune) currently support marketing boards. Both pear and apple growers (crops that are split between processing and fresh markets) currently support marketing boards, although their influence is limited by insufficient funds available for research and marketing. Cherry is the only fresh market fruit crop grown in California that currently supports a marketing board with funding available for research programs. California peach, nectarine, and plum packers supported a marketing board, the California Tree Fruit Agreement (CTFA), for almost 100 years. However, in 2010 the CTFA was disbanded by members of the board. All attempts to organize an analogous apricot marketing board in the 1990s were unsuccessful. As a result, the California fresh market stone fruit industry is currently without consolidated domestic and international marketing programs and funding for research.

The lack of success in establishing and maintaining fresh market crop marketing boards is related to changes in these industries over the past 10 years. As the average farm size increases (McClarty *et al.*, 2007) and the number of small farms decreases (**Table 2**, McClarty *et al.*, 2007; Perez and Ali, 2009) there are fewer entities governing the fresh market tree fruit industry. This results in increased competition among large fresh market growers and packers with less incentive to fund widely available research and marketing programs that could give competitors an advantage in production, domestic, and international sales. Without consolidated marketing and research, fresh market crop growers must rely entirely on research conducted by increasingly large private companies and dwindling research programs in universities and the USDA.

Manual Labor Requirements, Harvest Technology, and Quality Standards

Tree fruit and nut crop production requires substantial manual labor throughout the year for pruning, pest management, fertilizer application, irrigation, and harvest (Martin and Calvin, 2011). On an average, specialized fruit and nut tree farms allocate 48% of variable cash expenses each year to pay for labor to maintain and harvest their crop. The second greatest expense for fruit and nut tree farmers is fertilizers and chemicals (15% of variable cash expenditures, Perez and Ali, 2009). As a result of increasing costs of manual labor and insurance, fruit and nut tree growers have modified many aspects of production to reduce labor requirements and increase mechanization. The extent to which fruit and nut tree growers have been able to reduce labor costs, and mechanize their operations, differs substantially between fresh market and commodity crops.

Manual Labor Requirements: Fresh Market Crops

The primary fresh market tree crops grown in California (freestone peach, nectarine, cherry, and plum) require substantial manual labor inputs throughout the year to maximize fruit quality and meet strict quality and grading standards set for fresh market produce. Fresh market fruit crop value is determined, in part, by fruit size, presence of blemishes or bruises, ripeness, and color. Each of these strict quality standards results in manual labor requirements for the typical fresh market fruit grower during fruit thinning, harvest, and pruning.

Fruit size

Fruit size is inversely related to the number of fruits on a tree. As a result, fresh market crop growers typically thin blossoms or young fruit to maximize individual fruit size. Hand flower and fruit thinning is very costly and a substantial amount of research has focused on finding a viable mechanical or chemical alternative. Research into mechanical and chemical thinning options has demonstrated the feasibility of some techniques and significant savings associated with reduced manual labor requirements (Baugher *et al.*, 2010; Glenn *et al.*, 1994; Schupp *et al.*, 2008).

Fruit blemishes, color, and ripeness

Fruit blemishes, color, and ripeness are primary determinants of fresh market crop value. Fresh market produce is fragile and requires careful handling to avoid bruising and blemishes. Additionally, the color and firmness of individual fruit must be inspected to determine whether it is at the appropriate stage of maturity for harvest. In general, the careful handling and individual fruit observation required to meet fresh market quality standards are only possible through the use of manual labor during harvest. Despite research to develop mechanical harvesting capabilities for fruit crops (Glenn *et al.*, 1995; Torregrosa *et al.*, 2006, 2008; Zhao *et al.*, 2013), there is currently no technology available that can efficiently assess the ripeness stage of individual fruit and handle fruit in a way that minimizes damage.

Pruning to enhance fruit color and canopy size control

Two important goals in fresh market fruit tree pruning are (1) maximizing light interception by fruit to enhance color (an important component of fruit quality) and (2) reducing canopy size. Fresh market fruit require some direct light exposure to achieve proper color. Manual pruning is typically conducted annually to open the canopy, improve fruit and leaf light interception, and encourage renewal of fruit-bearing wood. Manual pruning is also used to limit canopy height and minimize the need for ladders during harvest. Although mechanical pruning options are available, they do not allow fresh market growers to achieve the required level of precision in pruning for canopy shape. Canopy size can be limited by grafting varieties onto size-controlling rootstocks. University of California and USDA research programs have been successful in developing new size-controlling rootstocks for peach and nectarine that do not limit average fruit size (Tombesi *et al.*, 2010; Weibel *et al.*, 2003).

Manual Labor Requirements: Fruit Commodity Crops

Commodity fruit crop growers in California have been successful in reducing manual labor expenses as a result of several important differences between the fresh and commodity crop

markets. The quality and grading standards applied to fruit used in processing are less stringent than fresh market requirements. As a result, less attention to detail is required in fruit thinning to manipulate average fruit size. In the cling peach and prune industries this means that some growers rely on mechanical or chemical thinning. Glozer and Hasey (2006) estimated that 31% of cling peach production costs have been allocated to hand thinning. As a result, transition to mechanical and chemical thinning can result in significant savings to growers in these industries. Cling peach, apple, pear, and apricot fruit must still be picked by hand at a specific stage of maturity, and handled with care to avoid damage that would render it unusable for processing applications. Although cling peach growers have reduced their reliance on manual labor to conduct some orchard operations, they are more dependent on hand labor than nut and prune commodity crops (see Section Manual Labor Requirements: Olive, Prune, and Nut Commodity Crops). Until mechanical harvesting technology improves to the point where it can efficiently locate and pick individual fruit, the requirement for hand harvesting will impose a significant constraint on the fruit commodity crop industries in California.

Manual Labor Requirements: Olive, Prune, and Nut Commodity Crops

Olive, prune, and nut growers have been the most successful of all California tree fruit and nut growers in minimizing manual labor expenses. The ability of these industries to significantly reduce manual labor is a result of differences in basic biology and industry requirements between most tree fruit and olive, prune, and nut crops. The relationship between fruit number and size in nut and olive crops is not as strong as with other fruit crops. As a result there is no need to thin flowers or fruit, eliminating a significant expense incurred in fresh market and commodity fruit crop industries. Although prune is typically thinned to increase average fruit size, California prune growers can thin the crop mechanically using trunk-shaking machinery (Buchner *et al.*, 2012).

Prune and nut growers have also eliminated the need for manual harvesting by using mechanical trunk shakers. Mechanical shakers attach to the trunk, or a main scaffold, and use vibration to dislodge fruit. Walnuts and almonds fall to the orchard floor and are collected later by mechanical sweepers. Pistachio and prune are caught in large mechanical frames with belts to load the crop into bins for transportation. Mechanical harvesting equipment has also been developed recently for the California olive industry. Mechanical olive harvesters use a rotating 'comb' to knock fruit out of the canopy into harvesting bins (Ferguson *et al.*, 2004). However, mechanical harvesting has not been adopted by the entire olive industry and some orchards are still harvested by hand.

Mechanical harvesting by trunk shaking has two financial benefits for growers: it reduces costs associated with hand harvesting and minimizes the need to control the size of trees by pruning. Because nut and olive crops do not require direct sun exposure to achieve necessary quality standards they do not require the same level of detailed hand pruning as in stone fruit. University of California research has demonstrated that regular pruning does not significantly increase yield or quality in walnut (Lampinen *et al.*, 2009, 2012) and almond (Curtis, 2012). After initial orchard establishment and manual tree training, prune, pistachio, and olive can be pruned using machinery or by hand, allowing a grower to decide how much of their budget to allocate to manual labor in a given year (Beede and Ferguson, 2005; Kreuger *et al.*, 2012; Sibbett, 2004).

Relationship between Manual Labor Requirements and Geographic Distribution of Fresh Market and Commodity Crop Industries

The southern San Joaquin Valley is a traditional center of fruit, nut, and vegetable agriculture in California. As a result, seasonal manual labor availability is greatest in this area. The uneven distribution of manual labor pools throughout California has a substantial impact on fresh market fruit production, which relies heavily on manual labor throughout the year for fruit thinning, harvest, and pruning. Small fresh market fruit growers located outside the southern San Joaquin Valley cannot provide long-term employment for manual laborers, and are less likely to find sufficient help to maintain and harvest their orchards. Most commodity crops have reduced their reliance on manual labor and are less constrained geographically to specific regions where many seasonal manual laborers are available. Small commodity crop growers can expand throughout the state because they utilize mechanical pruning and harvesting technology. Data on the distribution of tree crop production by county in California illustrate a broad and even geographic distribution of commodity crops (**Figure 2**). In contrast, fresh market crops tend to be more concentrated in the San Joaquin Valley, the historic center of agriculture in California (**Figure 3**).

Noneconomic Impacts on Fruit and Nut Tree Industries: Climate Change

Perennial crops are long lived: each year they produce new vegetative tissues that support growth and yield in the current season and in future years. Leaf and flower tissues develop in lateral and apical buds, and then expand to produce leaves and flowers the following growing season. Because woody and vegetative tissue is carried over across years, the growth, development, and yield of an individual tree are influenced both by the environmental conditions encountered in the current year and those encountered in previous years when structural biomass and buds are produced. Most fruit and nut orchards in California are maintained for at least 20 years. Orchard management decisions (including irrigation, fertilization, and pruning) and weather patterns can have substantial impacts on current tree growth, and yield in subsequent years. Despite the potential impact of climate change on perennial tree crops in California, research focused on understanding potential sources of risk is relatively new.

Analyses of Historic Climate Data Reveal Significant Changes in Temperature and Precipitation

Analyses of historic climate data in California demonstrate a significant 1 °C increase in annual mean temperature over the

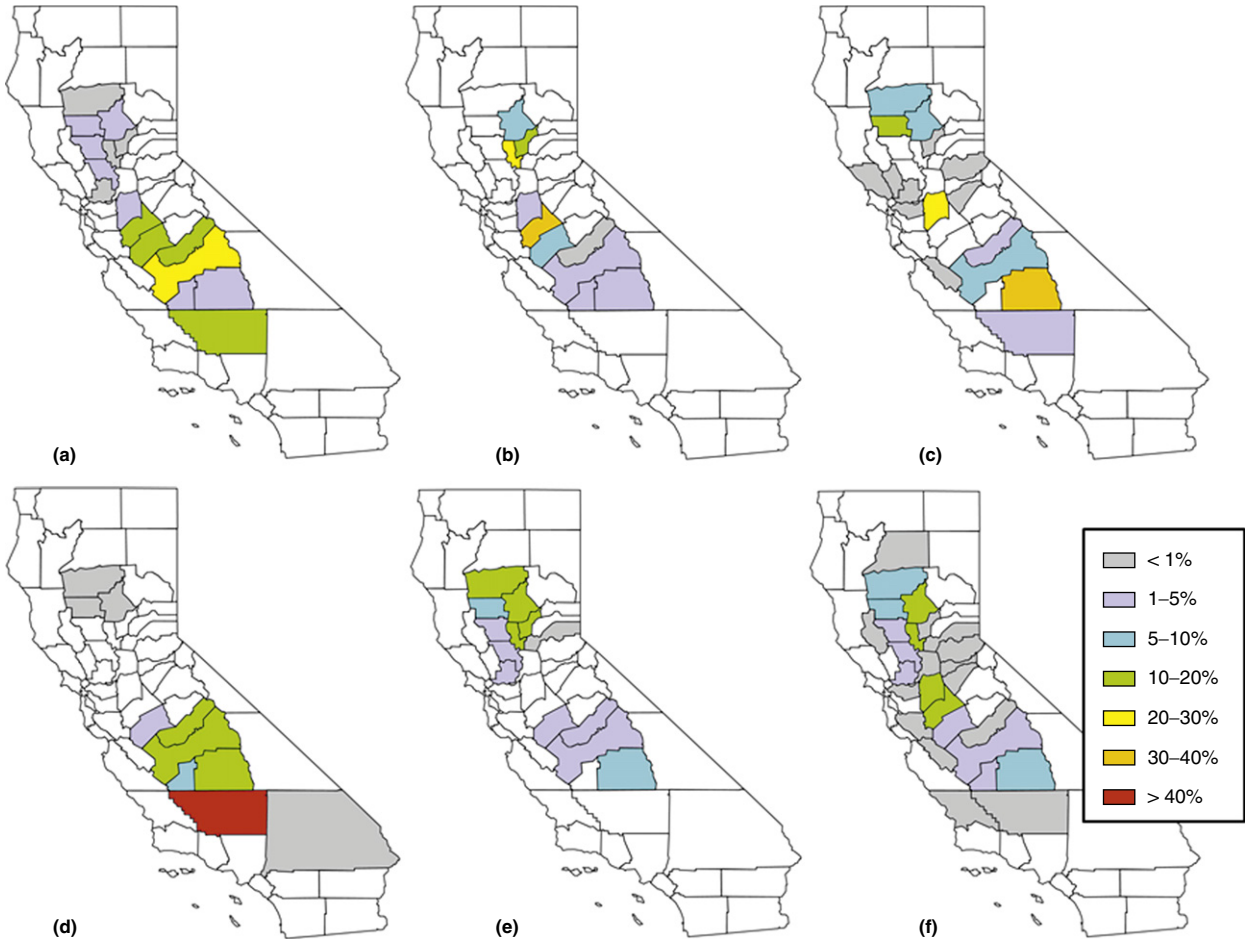

Figure 2 Geographic distribution of commodity crop production in California. Colors indicate the percentage of total statewide production reported in each county to local Agricultural Commissioners in 2011. Six major commodity tree crops are shown: almond (a), cling peach (b), olive (c), pistachio (d), prune (e), and walnut (f). Raw data were obtained from California County Agricultural Commissioners.

past 100 years. Observed long-term changes in temperature are a result of increased annual mean minimum temperatures and reduced variability in minimum temperatures (Anderson *et al.*, 2008). Between 1950 and 2000 mean and maximum daily temperatures increased in late winter and early spring. Additionally, minimum daily temperatures increased between September and January (Bonfils *et al.*, 2008). As a result of observed historic changes in temperature in California, several studies have used climate change models to anticipate future changes in temperature. Depending on the specific climate change scenario applied, average annual temperature is expected to increase between 1.5 and 4.5 °C over the next century (Cayan *et al.*, 2008).

In addition to changes in temperature the variability of precipitation (coefficient of variation) has increased significantly over the past 20 years, potentially resulting in earlier onset of snowmelt and diminished ability to store water reserves (Anderson *et al.*, 2008). Analyses of future climate change scenarios predict water availability deficits for both urban and agricultural users by 2065. Analyses using the most moderate climate change model predict severe agricultural water deficits in Southern California and the San Joaquin Basin (29% and 20% water deficits) with more moderate deficits in the Tulare Basin and Sacramento Valley (12% and 2%; Medellin-Azuara *et al.*, 2008). It is likely that California perennial crops, which use large amounts of water, will be vulnerable to prolonged water deficits predicted with climate change unless more efficient irrigation technology is developed (Jackson *et al.*, 2011).

Anticipated Effects of Climate Change on Tree Phenology and Yield in California

Changes in annual average temperature and winter minimum temperatures are likely to impact many different types of agricultural crops currently grown in California (Jackson *et al.*, 2011). Deciduous trees, including all of the major fruit and nut crops grown in California, require a period of cold over the winter to break dormancy and produce adequate yields the following year (Luedeling *et al.*, 2009). This cold requirement during dormancy is referred to as 'winter chill.' Winter chill is quantified using statistical models that count the number of hours below a threshold temperature in winter. Analyses of projected climate change scenarios using the four primary models (Utah, Dynamic, Chill Portions, and Positive Utah models) all predict decreases in winter chill over the next

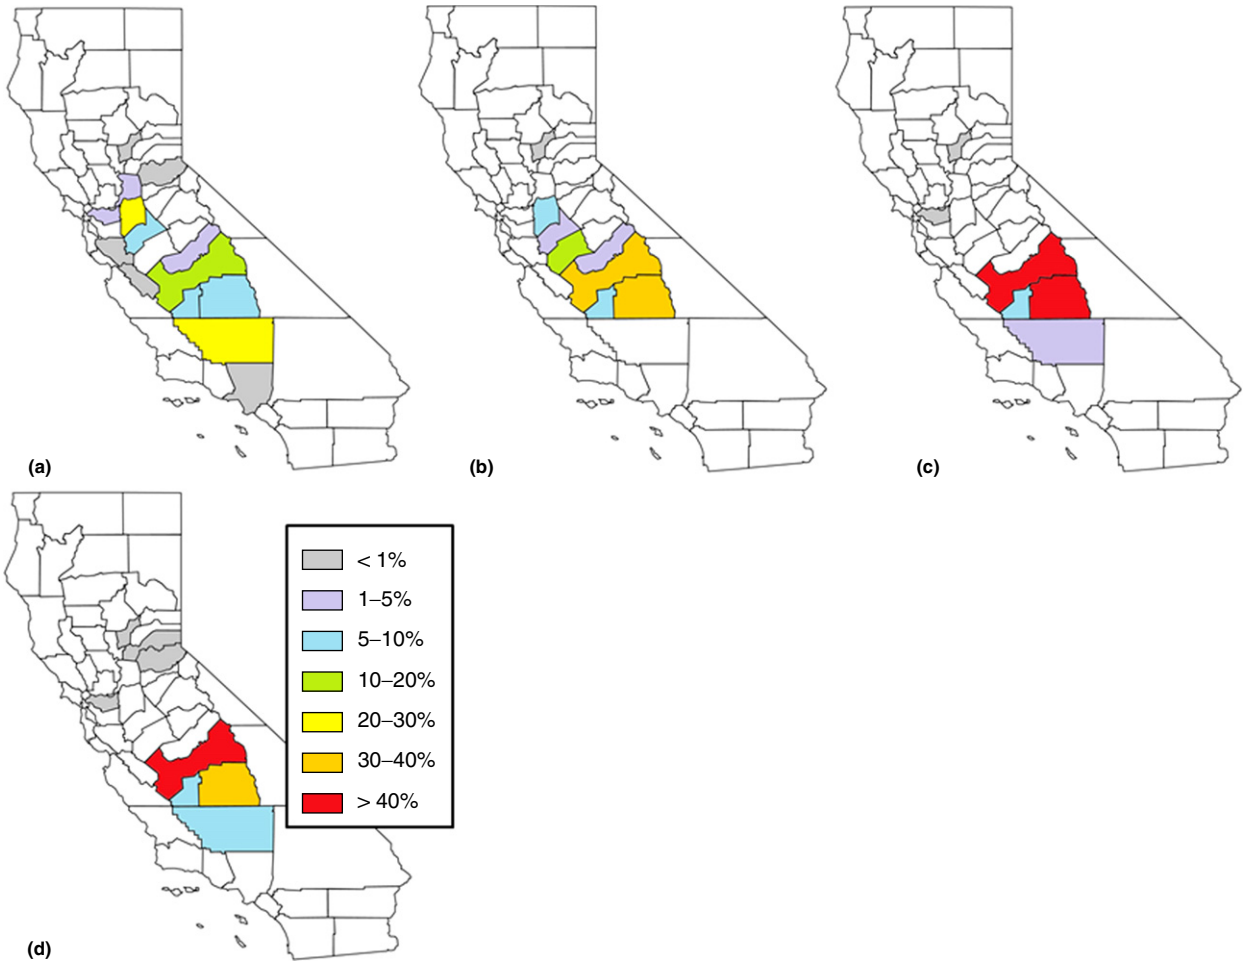

Figure 3 Geographic distribution of fresh market crop production in California. Colors indicate the percentage of total statewide production reported in each county to local Agricultural Commissioners in 2011. Four fresh market tree crops are shown: cherry (a), freestone peach (b), nectarine (c), and plum (d). Raw data were obtained from California County Agricultural Commissioners.

100 years in California, although predictions vary between models (Luedeling *et al.*, 2009). Analyses of long-term datasets demonstrate significant changes in the timing of leaf out and bloom in California walnut orchards as a result of increasing temperature (Pope *et al.*, 2013). Additional research is required to refine existing chill models to better understand specific future impacts on tree crop agriculture in California and resolve discrepancies among chill model predictions (Luedeling *et al.*, 2011). However, based on broad consensus across models, it is likely that breeding of new cultivars with low chill requirements, manipulation of orchard microclimate, and the use of rest-breaking agents will become important climate change adaptation tools for the tree crop industries in California over the next 100 years (Luedeling, 2012).

Potential Effects of Climate Change on Tree Crop Pests and Food Safety

In addition to the direct effects of climate change on tree crops (reduced winter chill and water deficits), long-term changes in precipitation and temperature could impact other organisms associated with fruit and nut tree agriculture including pests and pathogens. The distributions of agricultural pests, including annual weeds, have been shown to shift in response to changes in temperature and climate. These observations suggest that increased warming could result in shifts of southern pests into northern growing regions in California (Jackson *et al.*, 2011). Additionally, warmer winters and longer spring and summer conditions may result in reduced over-winter insect pest mortality and provide longer growing seasons for insects and more generations per year (Jackson *et al.*, 2011). The rate of illness associated with common foodborne pathogens, including *Campylobacter* and *Salmonella*, increases with average temperature worldwide (Tirado *et al.*, 2010). Because the relationship between pathogen-related illness and temperature varies among organisms and regions additional research in California is required to identify specific risks and solutions. Chemical prices have increased substantially over the past 10 years and constitute the second greatest annual expenditure for fruit and nut growers (Perez and Ali, 2009). An increase in pest damage and pathogen prevalence is likely to result in reduced yield and increased economic hardship for growers without proactive research to identify new control measures.

Parallel Trends in Tree Fruit and Nut Agricultural Regions Around the World

Many of the same factors driving shifts in tree fruit and nut agriculture in California are apparent in the other primary growing regions worldwide, including China, Chile, South Africa, Australia, and New Zealand. Production costs of both tree fruit and nut crops are rising worldwide. Increased production costs outside the US are primarily the result of rapid increases in wages for manual labor, as observed in China and Chile (Scott *et al.*, 2012, 2013). Because growers in China and Chile have not been able to mechanize operations for commodity crops to the extent that California growers have, this represents a serious threat to the industries in both regions. Production costs associated with pesticides, fertilizers, germplasm, and trellis systems can have an additional impact on growing trends. In China, a shift from peach to cherry production has been attributed to reduced pesticide and fertilizer use in cherry (Scott *et al.*, 2013). In South Africa, the average age of tree fruit acreage is increasing (25 years), with fewer new plantings, due to increased orchard establishment costs (Pickelsimer, 2013).

As in California, long-term price trends in China are an important driver of acreage and production of individual tree fruit and nut crops. For example, Chinese peach and nectarine acreage has been steadily declining as a result of decreased profit margins in favor of cherry acreage. Cherries receive a significant price premium by Chinese consumers, increasing the profitability of this industry to the extent that greenhouse cultivation is being used, despite the high overhead costs associated with establishing a greenhouse-grown orchard (Scott *et al.*, 2013). In South Africa, the price premium available for fresh market pear and apple growers has limited sales to processing industries to fruit that do not meet fresh market quality standards (Pickelsimer, 2013).

As tree fruit and nut growing regions worldwide expand their markets they are developing consolidated marketing groups to better communicate with increasingly consolidated food retail markets. In China, new government- and grower-run marketing cooperatives are being established to improve postharvest chain handling and increase competitiveness when compared to the US produce (Scott *et al.*, 2013). Growers in Australia, New Zealand, and South Africa also rely heavily on exports. Australian growers are in the process of transitioning from direct marketing between growers and retailers to a more consolidated system with strong marketing associations and grower groups (George, 1999).

One primary difference between California and other fruit and nut growing regions worldwide is the influence of local and national governments on production trends and costs. In China, the national and local governments have provided substantial subsidies to encourage walnut and almond planting in previously uncultivated or very steep terrain. It is estimated that a typical grower receives a government subsidy of $432 per acre to plant walnuts in China (Scott *et al.*, 2012). Government pressure and financial incentives to plant walnuts and almonds have dramatically increased acreage of both crops in China over the past decade. In contrast, Chilean tree fruit agriculture is currently faltering due to poor weather conditions and an almost 90% increase in labor costs over the past 10 years. This has generated a strong call for government support of this important industry, which employs almost 20% of Chilean labor.

Conclusions

The tree fruit and nut industry in California has shifted substantially over the past 30 years in response to long-term trends in crop value (**Table 1**) and consolidation in fruit packing and food retail industries (Johnston and McCalla, 2004; Linden, 2009). As a result of changes in these external factors the degree of competition among individual farmers, opportunities for small growers, research and development programs, and orchard management practices have shifted substantially. The specific impacts of long-term crop values and industry consolidation on individual growers differ between fresh market crops and commodity crops.

There are three factors unique to fresh market fruit crops that are imposing substantial constraints on the industry in California and in other parts of the world. First, fresh market fruit handlers and processors have undergone substantial consolidation over the past 15 years with fewer, larger packing houses available to purchase produce that conduct their own independent domestic and international marketing. As a result of consolidation in sales and marketing opportunities, competition among individual growers is high and there are fewer opportunities for small farms. Second, fresh market fruit industries are less willing to support crop-specific marketing boards to promote sales within the country and internationally as this responsibility shifts to large, consolidated marketing organizations. Without marketing boards or similar government-regulated entities there is less funding available for development of new cultivars and research to improve orchard management outside large private companies. Third, prices for manual labor and chemicals (pesticides and fertilizers) have increased substantially. Growers must rely on hand pruning and harvesting to ensure that fruit meet the high quality standards set for fresh market produce. Because manual labor is required for many farm operations year round, small farm profit margins are decreasing, making them more susceptible to year-to-year fluctuations in crop value and labor availability.

Commodity crop industries in California have expanded substantially over the past 30 years as a result of two favorable factors. First, all the primary tree fruit and nut commodity crops grown in California support marketing boards that conduct domestic and international marketing and promotion, as well as fund research and development. Marketing boards have been generally successful in increasing worldwide demand. Increased demand and independent marketing activities result in reduced direct competition among handlers and individual growers, and increased opportunities for small growers. Second, commodity crop growers have been successful in minimizing manual labor costs by transitioning to mechanical thinning and harvesting and using alternative pruning programs.

Tree fruit and nuts comprise a substantial proportion of agricultural production in the US. Both domestic and

international markets have played an important role in determining shifts in this industry over the past 30 years and will continue to do so. In addition to external market factors it is likely that tree fruit and nut agriculture will also be impacted by climate change in the next century as winter average temperatures rise, reducing chill hours available during dormancy, and water availability decreases and/or becomes more erratic.

Glossary

Antigen A substance which the body recognizes as alien and induces an immune response.

Cluster of differentiation (CD) A nomenclature system to identify and characterize cell surface molecules.

Cytokines A group of small proteins that is important in cell signaling. Cytokines include interleukins which are important in the regulation of immune responses. Proinflammatory cytokines are important during the inflammatory process directly after infection.

Dendritic cells Cells of the immune system which process antigen and present it on the surface to other cells of the immune system.

Differentiating infected from vaccinated animals (DIVA) An approach in which animals are vaccinated with a vaccine that can be differentiated from infections with field virus by serological or other methods.

Major histocompatibility complex (MHC) A set of molecules displayed on cell surfaces that are responsible for lymphocyte recognition and 'antigen presentation'. The MHC molecules control the immune response through recognition of 'self' and 'nonself,' and consequently, serve as targets in transplantation rejection.

Pathogen-associated molecular patterns (PAMS) PAMS are molecules associated with groups of pathogens. PAMS include lipopolysaccharides, proteins, single stranded RNA fragments, and nonmethylated CpG DNA sequences. PAMS bind to pattern recognition receptors which is important for the initiation of immune responses by the host.

Pattern recognition receptors (PRR) Proteins expressed by cells of the innate immune response. PRR can be expressed on the cell surface and in the cytoplasm. Toll-like receptors are a specific group of PRR.

Quantitative trait loci (QTLs) Stretches of DNA containing or linked to the genes that underlie a quantitative trait.

Toll-like receptors (TLR) A specific group of PRR (see Pattern Recognition Receptors), TLR are evolutionary preserved and were first recognized in the fruit fly (see Pathogen-Associated Molecular Patterns).

Introduction

The projected increase in human population from 6.8 billion in 2010 to more than 9 billion in 2050, combined with the increase in disposable income in countries such as China and India, will have a major impact on the increased need for animal protein for human consumption. The current production of animal protein for human consumption is projected to continue increasing until 2050 (Table 1). To achieve these predicted increases it will be of crucial importance to improve feed conversion, production parameters, and genetic resistance to disease as well as control exposure to pathogens by improved biosecurity and vaccination.

The focus of this article is mostly on vaccines and vaccination technologies used in aquaculture, poultry, swine, and cattle. Unless specifically mentioned as a category, these four groups are referred to as production animals. Although small ruminant production is expected to increase until 2050 (Table 1), the amount of small ruminant products is dwarfed by the other four commodities, and vaccination of small ruminants is not covered here. Because vaccine-induced protection depends on the degree of genetic resistance to a given pathogen and on the degree of biosecurity, these topics are briefly addressed. In addition, the major groups of pathogens and immune responses relevant to vaccine-induced immunity are briefly reviewed.

There are several extensive publications on the production and quality control of vaccines, the use of vaccines, and related topics. For more detailed information see Gay *et al.* (2007), Jones *et al.* (2007), Lombard *et al.* (2007), Lubroth *et al.* (2007), McLeod and Rushton (2007), Scudamore (2007), O'Brien and Zanker (2007), Schat and Baranowski (2007), and Schudel (2007).

Pathogens

For the purpose of this article pathogens are defined as organisms infecting production animals, leading to disease or causing immunosuppression that leads to increased

Table 1 World production of meat, milk, eggs, and aquaculture from 1961 to estimates for 2050

Commodity	*Production in million tons*						*Increase from 2011 to 2050 (%)*
	1961/1963[a]	*2005/2007*[a]	*2011*[b]	*2012*[b]	*2013*[b]	*2050*[a]

susceptibility to infection and disease by other pathogens. Three broad categories of pathogens are relevant to this article: viruses, bacteria, and parasites. The latter category includes protozoa as well as helminths. Fungi constitute a fourth group of pathogens but are not discussed as there are no antifungal vaccines available for production animals. Research to develop vaccines for humans against *Candida albicans* and other fungal infections (Cassone, 2013; Spellberg, 2011) may lead to antifungal vaccines for use in production animals in the future.

Detailed descriptions of human and animal pathogens can be found in several textbooks, such as Medical Microbiology (Murray *et al.*, 2012), Veterinary Microbiology and Microbial Disease (Quinn *et al.*, 2011), and Georgis' Parasitology for Veterinarians (Bowman, 2014). A short description of viruses, bacteria, and parasites relevant for this article is provided for readers not familiar with the key characteristics of these pathogens.

Viruses

Viruses infecting production animals are small (15–300 nm) and cannot be seen by light microscopy with the exception of poxviruses. Viruses are inert outside of living cells and are strictly intracellular pathogens. Entrance into living cells is essential for their replication using cellular organelles for the production of viral proteins. Viruses have double-stranded (ds) or single-stranded (ss) deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) genomes but never both. Some of the larger viruses have genomes coding for proteins that are needed for genome replication (e.g., poxviruses and herpesviruses), whereas other viruses depend on cellular enzymes to replicate their genomes. The genome is surrounded by a capsid that consists of proteins or sometimes by a lipid membrane derived from the host cell, which is referred to as the envelope. Viral proteins are inserted in the envelope during the development of virus particles. Enveloped viruses are in general susceptible to inactivation by disinfectants and external factors, such as sunlight, whereas viruses with only a protein capsid are more resistant to chemical and physical treatments, which have important consequences for biosecurity measures.

Bacteria

Bacteria are classified as prokaryotic cells lacking a nucleus and organelles in the cytoplasm. Individual bacteria range in size from 1 to 20 μm, but they can form clusters, chains, or biofilms. Bacterial genomes consist of a single ds DNA chromosome, which is often circular but can be linear. Bacteria reproduce by cell division. Small circular, autonomously replicating DNA sequences called plasmids may be present. These plasmids can contain virulence factors and sequences conferring antibiotic resistance. Plasmids can be exchanged between bacteria of the same or different species. Most bacteria have a rigid cell wall and may have flagella or fimbria. The composition of the cell wall is important for a broad classification into two groups: Gram-positive and Gram-negative bacteria. The only important pathogenic bacteria lacking a rigid cell wall are the Mycoplasmas, which have a plasma membrane. Some bacteria (e.g., *Bacillus antracis* causing antrax) produce endospores that are extremely resistant to chemical or physical treatments and can remain dormant for very long periods. The classification of bacteria was traditionally based on morphology, culturing on different media, motility, and metabolic activity, which all required the ability to grow the bacteria in inert media. With the advance of next generation sequencing, classification of bacteria can be achieved to the level of strain identification using the 53 genes coding for ribosomal protein subunits (ribosomal multilocus sequence typing (rMLST)) (Jolley *et al.*, 2012).

Parasites

This widely divergent group of organisms includes unicellular organisms, such as coccidia, Plasmodium, and *Theileria parva*,

as well as multicellular organisms that can vary tremendously in size, including 10-m long tapeworms. All organisms in this group are eukaryocytes with a defined nucleus including a nuclear membrane and with different organelles in the cytoplasm. The life cycle of parasites can be very complex, including sexual and asexual reproduction. Several economically important parasites affecting production animals have intermediate hosts (e.g., ticks for *T. parva*), whereas others do not use intermediate hosts (e.g., *Eimeria* species in chickens).

Relevant Immune Responses

To discuss vaccines and vaccination it is important to provide a brief overview of the major immune responses. A good introduction to the basics of veterinary immunology can be found in 'Veterinary Immunology: Principles and Practice' (Day and Schultz, 2011); more in-depth information is provided in 'The Immune System, third ed.' (Parham, 2009). Both books are focused on the immunology of mammalian species. Readers interested in the immunology of birds or teleost fish may consult 'Avian Immunology, second ed.' (Schat *et al.*, 2014) or 'Fish Defenses, vol. 1: Immunology' (Zaccone *et al.*, 2008), respectively. Most of the information on mammalian immunology is based on studies in mice or humans, whereas avian immunology is largely based on studies in chickens. Within these two classes of animals, major differences may exist among species of the same class. Similarly, major differences are expected to exist among the approximately 4000 teleost fish species. Key differences between the three classes of animals and, if appropriate, within classes are indicated.

Immune responses are often divided into innate and acquired (also called adaptive) immune responses, but this division is no longer seen as an absolute. Innate immune responses, although capable of directly killing microbes, are also absolutely required for the generation of adaptive immune responses. This is achieved by specific 'pattern recognition receptors (PRR)' that are located on the cellular membranes and in the cytoplasm of the cells. Toll-like receptors (TLR) are an example of PRR and were originally described in the fruit fly (*Drosophila melanogaster*). PRRs recognize specific 'pathogen-associated molecular patterns (PAMPs).' PAMPs are conserved among classes of microbes but should not be confused with virulence factors. Binding of PAMPS through TLRs or other PRR on the so-called professional antigen-presenting cells (APC), such as dendritic cells and macrophages or infected cells, results in the production of specific cytokines or interleukins (ILs) by APC. The ILs activate lymphocytes starting the activation of the adaptive immune system.

Innate Responses

Innate responses are activated rapidly within minutes to hours after an infection and have limited specificity and lack of memory. Pathogens first encounter physical and chemical barriers at the skin and epithelial surfaces in the respiratory and intestinal tracts. Mucus on the skin of fish as well as in the upper respiratory tracts acts as a chemical barrier, can trap pathogens, and prevent infection. If a pathogen successfully overcomes the physical barriers, it meets cells of the innate immune system that are equipped with secreted and cell-associated defense mechanisms. Soluble defenses induce inflammation and include interferons (IFN), defensins, and complements. Complement can promote phagocytosis by cells such as neutrophils (called heterophils in birds) and macrophages, which initiate cell-associated defenses, such as nitric oxide (NO) production. Natural killer (NK) cells exhibit both innate and adaptive-type responses. NK cells can kill tumor and virus-infected cells and are an important source of IFN-γ, which also enhances macrophage and neutrophil phagocytosis and microbial killing. Most of these innate responses are very similar in teleost fish, birds, and mammals, although minor differences among these three groups may exist.

Although innate immune responses are important for the initiation of vaccine-induced immunity, they are generally not considered important vaccine immune responses due to the lack of memory and specificity. However, in intensive production systems, such as the chicken broiler industry, vaccination especially with live attenuated vaccines may briefly boost innate responses, which can have a beneficial protective effect before the development of an adaptive, protective immune response. For example, in chickens, NK cells are activated after vaccination against Marek's disease (MD) herpesvirus (MDV) (Heller and Schat, 1987) and based on studies by Garcia-Camacho *et al.* (2003) may provide protection during the first few weeks when the birds are in the poultry houses. MD is discussed in more detail in the another article of this Encyclopedia.

Antibody Responses

The adaptive immune responses can be divided into antibody and cell-mediated responses. On exposure to an antigen (in this article typically a protein-based part of a pathogen) antibodies are generated by B lymphocytes, which may develop into plasma cells producing large quantities of antibodies. Immunoglobulins (Ig) consist of heavy chains and light chains. IgG (see below) consists of two heavy and two light chains, which represents the basic structure of an immunoglobulin. The heavy chains have a number of constant domains and one variable domain, whereas the light chain has one constant and one variable domain. The variable domains of the heavy and light chains form the antigen-binding site, whereas the constant domains of the heavy chain are important for additional functions, such as activation of complement or binding to cellular receptors. For further details on the general aspects of antibodies, the readers are advised to refer to the different textbooks mentioned earlier.

There are a number of different antibody classes and subclasses that vary among the teleost fish, birds, and mammals (**Table 2**). For the purpose of this article, the author has focused on the IgG, IgM, and IgA antibodies, or their equivalents. IgG (often referred to as IgY in birds) consists of two heavy and two light chains. It is the dominant antibody in serum and depending on the immunization schedule and vaccine used it is the key antibody produced in vaccine-induced, antibody-based protective immunity. After a primary infection or first vaccination, IgG antibodies are detected approximately 7 days postinfection (pi), which is named the primary response. One of the hallmark characteristics of an

Table 2 Antibody classes and subclasses in cattle, swine, chickens, and teleost fish

[a]Tetramer in fish and pentamer in birds and mammals.
Abbreviation: Aka, also known as.

acquired immune response is memory. Memory B cells are generated during the primary response, and on second exposure to the same antigen, they are responsible for a rapid increase of IgG antibody production. This is called the secondary response and is generally long lasting. These characteristics form the basis for vaccination.

Other classes of antibodies include IgM and IgA. IgM consists of five basic structures (pentamer) except in fish, which have tetrameric IgM-like antibodies. IgM antibodies are the first class that can be detected after exposure to a pathogen and are typically not detected in a secondary response. However, IgM is the major antibody response to pathogens in fish. IgA is important for mucosal immunity. IgA can exist as a monomer or a dimer joined by the so-called J chain. In addition, dimeric IgA is associated with a protein, the secretory component, which protects the antibody against degradation by proteolytic enzymes at mucosal surfaces. Fish lack IgA but produce IgT, which performs similar functions to IgA and is present in relatively large quantities in the skin mucosa.

Cell-mediated Immunity

Cell-mediated immune (CMI) responses are especially important for the control of intracellular pathogens and are primarily mediated by cytotoxic T lymphocytes (CTLs). CTLs have been described in all production animals from fish to cattle and swine and are characterized by the surface markers CD8α and CD8β. These cells recognize small antigen fragments of 8–12 amino acid peptides if these fragments are presented in the context of major histocompatibility complex (MHC) class I proteins, which are expressed on the surface of virtually all cells in the body. When CTLs recognize a small peptide expressed in the context of MHC class I, they kill the cells presenting the antigen through a rather complex system, eliminating pathogen-infected cells. Memory responses have been described for CTL; thus, once an animal has been immunized and a CTL response has been generated, antigen-specific CTL can rapidly expand after subsequent exposures, similar to memory antibody responses.

Antigen Processing

To understand the differences in immune responses generated by live versus inactivated (also referred to as killed) vaccines it is important to briefly discuss antigen processing. When a killed vaccine or an antigenic protein is injected into an animal it is typically processed by professional APC. The proteins are broken down in the phagolysosome of the APC to fragments of mostly 10–30 amino acids, which are then presented to B-lymphocytes in the context of MHC class II antigens on the cell surface of the APC. In mammalian species this process occurs in the lymph nodes. Chickens lack lymph nodes and antigen processing occurs mostly in the spleen.

Antigen processing for presentation to CTL differs fundamentally from the processing for presentation to B lymphocytes. For CTL presentation, *de novo* synthesis of proteins is needed, i.e., replication of virus, intracellular bacteria, or protozoa in an infected cell is needed for optimal presentation of antigen to CTL. The newly synthesized pathogen-derived proteins are broken down to small peptide fragments in the cytosol and are transported into the endoplasmic reticulum, where they bind to the MHC class I molecules. These MHC class I–antigen complexes are then transported via the Golgi apparatus to the cell surface for CTL recognition. The practical consequences for vaccinology are that inactivated vaccines induce antibody responses with little or no CMI responses, whereas live vaccines generate both antibody and CMI responses.

Maternal Immunity

The immune system of newborn animals is generally poorly developed and requires time to fully mature after birth. To protect the newborn against infections, antibodies are transferred in mammals from the dam to their offspring through the placenta or the colostrum. There is little or no transfer of IgG through the placenta in cows and sows; thus, it is of crucial importance that newborn calves and piglets receive colostrum during the first 24–48 h after birth (Butler, 2006). The neonatal intestinal tract of many mammals, including cattle and swine, allows efficient absorption of Ig only during the first 24–48 h after birth. In cows, the unique IgG subclass 1 is the major antibody in the colostrum. The intestinal tract allows the absorption of Ig in calves and piglets only during the first 48 h after birth. Sow colostrum consists of 60% IgG, 30% IgA, and 10% IgM. After 48 h the composition of immunoglobulins in sow milk changes to predominantly IgA. (Butler *et al.*, 2006). Maternal immunity in chickens is provided through transfer of IgY from the yolk to the embryo and newborn chicken. Although maternal immunity has been described for fish (Zhang *et al.*, 2013), the level of transfer of maternal antibodies to Atlantic salmon (*Salmo salar* L.) fry is apparently insufficient to provide protection against infection with *Yersinia ruckeri* (Lillehaug *et al.*, 1996). The importance of

maternal immunity for vaccination schedules is discussed in the Section 'Selected Examples of Vaccinations in the Four Groups of Production Animals.'

Immunosuppression and Immunoevasion

Many factors can influence the immune response to a given vaccine, especially in the more intensive production systems of swine, poultry, and fish units where large numbers of multiple age groups are kept in high density in confined spaces (e.g., the chicken layer industry). Stress levels can be high under these conditions and immunosuppressive viruses (e.g., chicken anemia virus and infectious bursal disease in chickens and porcine circovirus in piglets) often cause subclinical immunosuppression resulting in suboptimal protection after vaccination. In addition, a number of pathogens have developed strategies that interfere with immune responses. Poxviruses, herpesviruses, coronaviruses, and orthomyxoviruses have been especially successful in developing immune-evasive approaches, which have been well documented for chicken pathogens (reviewed in Schat and Skinner, 2014).

Importance of Biosecurity

Biosecurity is defined here as the complex of precautions taken to protect against the introduction and spread of harmful organisms and diseases into or within animal production systems. Some producers of production animals believe that vaccine manufacturers can always produce better vaccines and therefore biosecurity is not very important or is even irrelevant. However, the use of vaccines can never be an excuse for poor biosecurity. Most vaccines do not provide a sterilizing immunity, meaning that vaccination may prevent disease but not prevent replication of pathogens. As a consequence escape mutants may arise for which the vaccine no longer provides protection. Premises that are poorly cleaned after a previous flock or herd has been removed may allow naïve animals to be exposed by residual pathogens before the immune response matures or before solid vaccinal immunity has been established. An example of good and poor farm management for poultry is provided in Figures 1(a) and (b), respectively. In Figure 1(b) there is no clean area directly adjacent to the poultry house. The absence of a clean area facilitates the entrance of rodents and other fomites. It will be much more difficult to control diseases under these circumstances even when vaccination procedures are correctly executed.

Ideally, closed houses with proper ventilation and climate control, which are cleaned and disinfected after each cycle, are used for chickens and swine, but this is often impractical in warmer climates, especially in economically poor countries. Multiage farms, a reality in most poultry production systems for layers, are another problem for strict biosecurity, preventing thorough cleanup of the premises.

Biosecurity measures that can always be included are as follows: restriction of access to the farm to only essential personnel, a change of boots and coverall before entering a chicken or swine house, and the use of proper footbath with disinfectant that is changed daily. It is important to ensure that vaccination crews and other persons visiting several farms on one day do not enter the facility without change of clothes and ideally a shower before entering the premises. A specific problem is encountered in several countries where most of the chickens are sold through live markets. Traders come to the farms to get their quota of birds, often using trucks that have not been cleaned for a long time. In this situation it is recommended that the farmer brings the birds to the entrance of the farm so that the trader does not have to enter with his truck. As a consequence of the bird flu situation, biosecurity measures have been more strictly enforced in the poultry industry over the past 5–10 years, but in many instances a critical evaluation by a qualified poultry veterinarian will result in recommendations for further improvements. For more detailed information on biosecurity measures for poultry production, the readers may refer to 'Diseases of Poultry, thirteenth ed.' (Collett, 2013). Many of the recommendations made for biosecurity on poultry farms are also applicable to intensive production systems for other food animals.

(a) (b)

Figure 1 Layer parent farm (a) and commercial layer farm (b) in India. Both are multiage farms with natural ventilation and curtains. Note the clean environment and cement borders around the building in (a) in contrast with the commercial farm with plants growing up to the building and junk lying around in (b).

Genetic Resistance to Disease

Several factors favor the inclusion of genetic resistance in disease control programs for the four major production animal groups (reviewed in Gay *et al.*, 2007). The first factor is the concentration of genetic stock within a limited number of companies. In the poultry industry, for instance, there are only a few major breeders left in the world. These breeders are maintaining pure genetic lines under constant selection pressure for multiple traits. To produce a commercial product (layers or broilers), eight lines are used basically following the outline in **Figure 2**. Introduction of and subsequent selection for a new trait in one of the eight lines, indicated by the asterisk in **Figure 2**, will result in the presence of the new trait 4 years later in the production animals. Similar trends in concentration of genetic stocks are evolving in the salmonid industry and have started in the swine industry.

A second factor is the use of artificial insemination. In dairy cattle this had far-reaching implications as is illustrated by the impact of an elite sire and son duo on the distribution of candidate genes related to important production traits, including disease resistance. Each of these two bulls accounts for approximately 7% of the current genomes (Larkin *et al.*, 2012). However, the use of a highly desirable sire can also introduce unexpected new problems, as is illustrated by the case of leukocyte adhesion deficiency (LAD) disease. LAD has been linked to a point mutation in the gene coding for the leukocyte adhesion molecule CD18, and this defect was traced back to a specific sire Osborndale Ivanhoe, who was used extensively as a semen donor in the United States (Shuster *et al.*, 1992). Once the defect was identified at the molecular level, the disease was eradicated. Several other genetic diseases linked to the widespread use of semen from a single bull are mentioned by Shuster *et al.* (1992). The increased use of embryo transfer will have similar positive and potentially negative effects.

A third condition favoring the inclusion of genetic selection for disease resistance is the rapid progress in new DNA sequencing techniques, which has resulted in the (near) release of complete genome maps for chickens, swine, cattle, and salmonids. Genetic resistance to pathogen-induced disease can be at the level of receptors preventing infection. For example, chickens can be resistant or susceptible to infection with avian leukosis virus subgroup A (ALV-A) based on allelic differences in the receptor gene (Nair and Fadly, 2013). The poultry breeders have used this information in their genetic selection program to generate birds resistant to ALV (McKay, 2013, personal communication). In swine, a single-nucleotide mutation at position 307 (G/A) of the alpha-(1,2)-fucosyltransferase (FUT1) gene, the putative receptor for F18 fimbriae of *Escherichia coli*, is strongly correlated with increased resistance to enterotoxigenic and verotoxigenic *E. coli* (Wang *et al.*, 2012). Atlantic salmon are highly susceptible to infectious pancreatic necrosis (IPN) virus, a birnavirus, which can cause 30–80% mortality during the juvenile posthatch freshwater stage. A quantitative trait locus (QTL) has been identified that confers resistance to the infection (Houston *et al.*, 2012; Moen *et al.*, 2009). Including the resistance conferring QTL in the breeding program by AquaGen in Norway has led to a dramatic reduction in the incidence of IPN (Anonymous, 2013b).

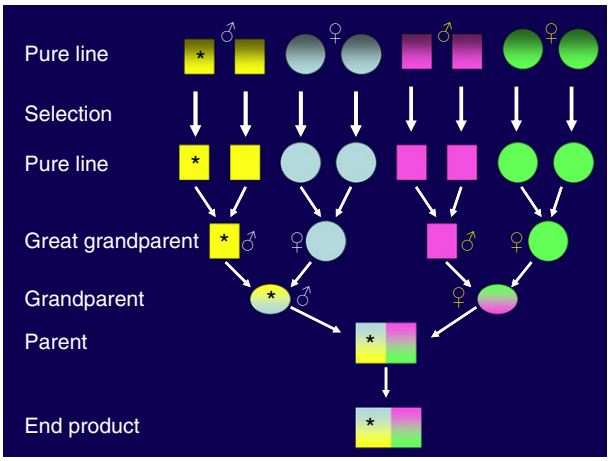

Figure 2 Breeding scheme used by primary poultry breeders to generate a commercial end product. The asterisk represents the introduction of a new trait and subsequent selection for the trait through the generations.

These examples suggest that transgenic approaches for disease control may be possible if regulatory and consumer resistance can be addressed. One example is the development of transgenic chickens that were unable to transmit avian influenza virus (AIV) to pen-mates, although the transgenic birds were not resistant to direct challenge. The resistance is based on the expression of a small RNA fragment that acts as a decoy to the viral polymerase complex (Lyall *et al.*, 2011). Transgenesis to increase resistance to specific diseases has been reported for several fish species (Dunham, 2009). Dunham suggests that the environmental risks of transgenic fish are minimal, but transgenic fish resistant to disease have not yet been used commercially. The Food and Drug Administration of the United States Department of Health and Human Services (FDA) has jurisdiction over the acceptance of transgenic fish for human consumption in the United States. In a preliminary document, the FDA concluded that transgenic Atlantic salmon containing the *opAFP-GHc2* recombinant DNA construct, produced by AquaBounty Technologies, are safe as a food source for human consumption.

Genetic resistance to certain diseases can also be based on the presence of specific MHC alleles or on the identification of QTL linked to resistance. For example, in chickens resistance and susceptibility to Marek's disease have been linked to the MHC complex (reviewed by Schat and Nair, 2013) and several QTL (Cheng and Lamont, 2013). In MD-resistant birds, viremia levels are lower than in susceptible birds during the first 14 days pi and vaccines provide better protection against virus replication in resistant than in susceptible chicken lines (Yunis *et al.*, 2004; Schat *et al.*, 1982). In a multigenerational challenge study using elite egg production pure lines, Fulton *et al.* (2013) reported an association between Marek's disease mortality and the MHC of the sire. This information combined with selection for production traits is actively used in the selection program to improve resistance to MD (Fulton *et al.*, 2013; McKay, personal communication). Because this type of selection experiment is not easily reproduced for other pathogens, selection for genetic control of immune responses is used rather than selection for resistance to specific pathogens

(Lamont *et al.*, 2014). In chickens, in addition to the QTL linked to MD resistance, QTL have been identified that are linked to resistance to Salmonellosis, *E. coli*, coccidiosis, and infectious bursal disease (Cheng and Lamont, 2013), but these QTL are currently not included in the breeding programs of at least one major breeder company (McKay, personal communication).

In conclusion, improvement in genetic resistance needs to be an important part of an integrated disease control program in conjunction with strong biosecurity measures and an optimal vaccine program.

Vaccines

To Vaccinate or Not to Vaccinate

It is generally accepted that the use of vaccines is an essential component of disease control, which also impacts the economic production and welfare of production animals. Although disease control is the main reason to use vaccines, there are several additional considerations when determining whether vaccines should be used (McLeod and Rushton, 2007). Of major importance are the restrictions on import and export of animals or animal products imposed by many countries. These exist as a consequence of the presence of specific diseases, such as avian influenza or foot-and-mouth disease (FMD). Vaccination results in the development of antibodies, which may not differ from antibodies present after infection, thus interfering with disease monitoring. As a consequence, countries may not want to import products that are antibody positive. Avian influenza not only causes major losses for the poultry industry but is also a zoonotic disease; however, FMD is an economically important disease that does not affect humans. In the case of avian influenza, some countries allow routine vaccination of poultry, whereas others rely exclusively on 'stamping-out' and inhibition of animal movement. In some countries, ring vaccination is allowed to prevent spread of AIV, whereas poultry flocks within the infected area are euthanized. This is especially attractive if a differentiating infected from vaccinated animals (DIVA) strategy can be used as is the case in avian influenza (Suarez, 2012; Capua *et al.*, 2003) (see Section Vaccines for Poultry). There is currently no DIVA strategy available for FMD (Clavijo *et al.*, 2004) and many countries rely, therefore, exclusively on stamping out; this has led to significant social problems as was the case during the 2001 outbreak in England (Scudamore, 2007). During this outbreak, the Netherlands used a ring vaccination to prevent the spread of FMD, euthanized all animals within the affected area, and subsequently destroyed the vaccinated (antibody positive) animals in order to be declared FMD free ('vaccinate to kill' policy) (Parida, 2009) (FMD vaccination is discussed in another article of this Encyclopedia).

McLeod and Rushton (2007) mentioned the possibility of eradication of a specific disease by international vaccination campaigns as a second reason to vaccinate. This approach has been successful in the case of rinderpest, a viral disease of cattle, which was officially declared eradicated in 2011 (Njeumi *et al.*, 2012). Other national or international campaigns are often initiated to reduce risks of transmission of zoonotic diseases to humans, for example, rabies and *Brucella abortus*, but these campaigns have not led to the global eradication of the diseases.

The third reason to vaccinate is to control economically important diseases. Decisions to vaccinate or not are often based on a cost/benefit analysis. For example, in the broiler industry, economic benefits were realized after the decision was made in 1983 to add the SB-1 vaccine strain to the herpesvirus of turkeys (HVT) vaccine against Marek's disease when HVT alone no longer fully protected birds against the disease. Within 3 months the industry had calculated that the addition of SB-1 was financially advantageous by reducing the condemnation rate of diseased birds (listed as leukosis in the USDA database on condemnations in poultry) enough to offset the increased vaccine costs. Another example is related to the overall costs of vaccines and medicines in relation to the overall production costs. The cost of all vaccines and medicines for an average broiler farm in the United States is US$ 0.05 per pound (=0.45 kg) live weight. In comparison, the chick cost is US$ 5.47 per pound live weight (Anonymous, 2013a), with profits ranging from approximately US$ 0.10 to a loss of US$ 0.01 per pound live weight. MD vaccines are the most expensive vaccines for broilers with the average prices in the United States ranging from US$ 2.65 per 1000 doses for HVT alone to US$12.00 per 1000 doses for HVT combined with the CVI988 vaccine strain (prices quoted for 2014). To reduce these costs, MD vaccines are often diluted, especially when the condemnation rates for 'leukosis' are very low (Schat and Baranowski, 2007; Schat and Nair, 2013). However, dilution of the vaccine reduces protection to virus replication and tumor development when birds are challenged with very virulent plus (vv+)MDV strains (Gimeno *et al.*, 2011) increasing the possibility of selection for more virulent strains (Atkins *et al.*, 2013).

Although vaccination of production animals against zoonotic and economically important diseases seems to be noncontroversial, there are some impediments, which are often regional. In Europe, consumers have expressed reservations about consuming meat from vaccinated animals, especially since the outbreaks of the highly pathogenic H5N1 avian influenza in poultry and the 2001 outbreak of FMD in the United Kingdom (Scudamore, 2007; O'Brien and Zanker, 2007). A second problem is related to the production and evaluation of vaccines that often involves animal testing for safety and efficacy, which has become problematic (O'Brien and Zanker, 2007). This is even more of a problem when new vaccines need to be developed for emerging or reemerging diseases. A third impediment is related to the control of transboundary diseases. Control of these diseases is frequently based on political decisions to vaccinate or to use 'stamping-out.' (Inter)national or regional vaccination campaigns may be needed if vaccination is allowed, which requires the willingness to commit economic resources and the cooperation of farmers. These conditions can be problematic, especially in politically unstable parts of the word (Lubroth *et al.*, 2007), but it can be done as has been shown with the eradication of rinderpest.

Characterization of Vaccines

Traditionally, vaccines have been developed by attenuating pathogens or using closely related agents that are not pathogenic in the target hosts. Since the advance in biotechnology,

vaccines have been developed using molecular approaches. In this section the author has first discussed the traditional vaccines and then the different approaches for biotechnology-based vaccines. Both categories can consist of live organisms or inactivated products. The latter group includes whole organisms, protein products, and DNA-based vaccines. A good overview of the different phases for the production of veterinary viral vaccines was recently published (van Gelder and Makoschey, 2012).

Determining vaccine efficacy

Independent of the type of vaccine, there is a need to establish methods for monitoring vaccine efficacy. When a new vaccine is submitted to the veterinary authorities, data are normally included showing protection against challenge. These tests are expensive and subject to animal use regulations, which vary among countries. To monitor vaccine 'takes' in field conditions, serology tests are most often used to determine whether adequate antibody titers have been achieved and are maintained over time. Most of these tests use different enzyme-linked immunosorbent assay (ELISA) approaches and commercial ELISA kits are available for most pathogens in cattle, swine, and poultry. Determining specific CMI responses is complicated and not used to measure vaccine responses. In chickens, a quantitative polymerase chain reaction (qPCR) assay can be used to determine whether the birds are adequately vaccinated by measuring CVI988, HVT, or SB-1 genome copies in the feather pulp between 7 and 14 days postvaccination (Baigent *et al.*, 2006; Renz *et al.*, 2013).

Traditional live vaccines

Most of the current vaccines for production animals are directed against viral and bacterial pathogens. Typically, a virus was isolated and passed a number of times in experimental animals, embryonated chicken eggs, or cell cultures, resulting in attenuation while remaining immunogenic. Probably the first example of attenuation of a virus was the use of rabbits by Pasteur to attenuate rabies virus (reviewed in Lombard *et al.*, 2007). Cell culture attenuation can be achieved by passaging the virus at its optimal temperature or at lower temperatures as has been done for the cold-adapted, live human influenza vaccine (Maassab and DeBorde, 1985). These approaches have been used successfully over the years, but the development of attenuated vaccines was empirical with often unpredictable results. Key requirements for the successful use of live virus vaccines are ease of (1) production, i.e., cell cultures using roller bottles or suspension cultures in bioreactors; (2) transport, i.e., liquid nitrogen (essential for Marek's disease vaccines), need of cold chain (either $-20\,^{\circ}C$ or $4\,^{\circ}C$, important for most vaccines), or ambient temperature (heat tolerant); (3) administration, and (4) good replication in the vaccinated animals without causing clinical or subclinical problems. The ease of administration is discussed in more detail in the Section 'Vaccination Procedures' and potential issues with subclinical problems discussed in the section on poultry vaccines. Production of live vaccines follows detailed protocols adhering to strict standards, which are determined by governments of individual countries (e.g., the Veterinary Services of APHIS-USDA), a group of countries (e.g., the European Union), or by the World Organization for Animal Health (OIE) (Jones *et al.*, 2007; Schudel, 2007).

Similar to viruses, bacteria have been attenuated by passage in animals or suboptimal culture conditions on artificial media. Pasteur and his coworkers have been credited with the production of an attenuated vaccine against swine erysipelas by passage of *Erysipelothrix rhusiopathiae* through rabbits and fowl cholera by using aged *Pasteurella multocida* cultures (reviewed in Lombard *et al.*, 2007). Bacterial vaccines are made in large bioreactors.

Different approaches have been used for some vaccines available for the control of unicellular and multicellular parasites (Lightowlers, 2014; Williams, 2002). Poultry coccidia vaccines have been developed by selecting precocious lines of coccidia, which replicate faster than wild-type strains and induce immunity without disease when given to young chicks. Control of lungworm, *Dictyocaulus viviparus*, in cattle is achieved by using irradiated attenuated L3 lungworm larva.

Since the advance in rapid sequence techniques, many of the attenuated vaccines have been properly characterized at the genomic level and shown to contain insertions or deletions. The finding of deletions has been helpful for the development of vaccines using recombinant technologies (see below).

Traditional inactivated vaccines

In general, the production of inactivated or killed vaccines follows similar guidelines, although somewhat more relaxed than for live vaccines. The more relaxed guidelines are best demonstrated for chicken embryo-produced killed virus vaccines. Although the production of live vaccines in embryos or chicken embryo-derived cell cultures requires the use of specific pathogen-free eggs, inactivated vaccines can be made in the so-called 'clean eggs,' which are not necessarily free of all pathogens. Inactivation can be achieved by several methods, such as treatment with alkylating agents (β-propiolactone and aminoethyl ethelene imines), different concentrations of formalin or glutaraldehyde, temperature, pH, and UV or gamma irradiation (Delrue *et al.*, 2012). Key concerns with the preparation of inactivated vaccines are immunogenicity and safety. Depending on the virus, some of the inactivation procedures damage the immunogenic epitopes, resulting in insufficient induction of protective immune responses. Viral safety can be compromised by incomplete inactivation of the vaccine virus or by the presence of extraneous pathogens in the cell culture media or embryos. Sera, trypsin, and embryonated chicken eggs can contain extraneous pathogens, some of which have only recently been described. The use of fetal bovine serum, for example, frequently results in contamination of vaccines with bovine viral diarrhea virus (BVDV). To avoid this problem, chemically defined cell culture media without animal components have been developed but may not be widely used for vaccines in, for example, the poultry industry. Another potential problem is incomplete inactivation of viruses belonging to the Circoviridae and the proposed new group of Anelloviridae. For example, chicken infectious anemia virus (CAV or CIAV) and porcine circovirus (PCV), belonging to the Gyrovirinae and Circovirinae subfamilies, respectively, of the Circoviridae are highly resistant to chemical inactivation (Schat and van Santen, 2013) and could remain present in inactivated vaccines. Application of PCR techniques has

become a major tool to determine the absence of known extraneous agents (Mackay and Kriz, 2010).

The choice of live versus inactivated vaccines

The choice between live and inactivated vaccines is not always simple and depends on many factors, such as the type of immune response that is required for protection. For example, a live vaccine will be preferred if cell-mediated immune (CMI) responses are essential for solid protection (see Section Antigen Processing), although inclusion of some adjuvants can stimulate CMI responses (see below). A live vaccine may also be preferred if mucosal antibody responses (IgA) are needed for protection. Production of IgA antibodies is stronger after natural exposure (see Section Vaccination Procedures) than after parenteral injection, which is typically used with inactivated vaccines. However, if IgG responses are critical for protection, inactivated vaccines will be highly effective, although adjuvants (see below) will be needed in most if not all inactivated vaccines.

In addition to the need to inject inactivated vaccines, which is a distinct disadvantage in the poultry and aquaculture industries, there is a second disadvantage: the need to produce high-titered products because there is no amplification of the vaccine in the vaccinated host. This is not always a problem; high titers can be obtained, especially when vaccines are made in embryonated chicken eggs. However, it makes the inactivated product more expensive than a live vaccine. Inactivated vaccines also have certain advantages over live vaccines. Because attenuation is not a linear process, live attenuated vaccines most likely contain populations that differ in the degree of attenuation, which may cause problems, especially if the animals are immunosuppressed by stress or subclinical immunosuppressive infections. Moreover, there is always the potential that the vaccine reverts back to become pathogenic or recombines with the wild-type viruses generating a recombinant. Live vaccines induce immune responses by replicating in the host, which can cause some degree of tissue damage. These vaccine reactions can be complicated by secondary infections leading to economic losses. Certain live vaccines are also contraindicated during pregnancies. None of these problems occur with properly inactivated vaccines except for some local tissue damage caused by adjuvants.

Inactivated vaccines are sometimes the only choice because virus cannot be attenuated as is the case for FMD. In other cases a new disease appears causing devastating losses, and a vaccine needs to be developed in a very short time span preventing the development of a live attenuated or recombinant vaccine. This was the case when Schmallenberg virus, a novel insect-transmitted Orthobunyavirus, appeared in 2011 in Europe, causing severe fetal malformation and still births in ruminants. The rapid development of inactivated vaccines has significantly reduced the impact of this pathogen (Wernike *et al.*, 2013). Autogenous vaccines are sometimes developed to solve local or regional problems by isolating the pathogen and producing a killed product. This type of vaccine is subject to authorization by the State Veterinarian in the United States.

If long-lasting immunity with high antibody titers is important, for example, for the transfer of IgY from the hen to her offspring through the yolk, a primer with a live vaccine followed by a killed vaccine is the best option. Boosting the immune response by second vaccination with a live vaccine is in general not recommended because the primary immune response will prevent replication of the booster vaccine.

Biotechnology-based vaccines

Since the advance in recombinant DNA technology several approaches have been used or proposed to produce new vaccines, but in actuality few have been authorized for use in the United States or elsewhere in the world. The following technologies have been used to develop commercial products: deletion mutants, vectored vaccines expressing antigens to different pathogens, subunit vaccines including virus-like particles (VLP), and DNA vaccines. The basic science on which these vaccines are based is briefly discussed in this section. More detailed information can be found in several review papers and the actual use in production animals is discussed in the four sections on vaccination in production animals. Many of the biotechnology-based vaccines can be used in DIVA strategies, and specific tests to differentiate between vaccine responses and pathogen infection are an integral part of the development of these vaccines. Tests include ELISAs as well as PCR-based assays. The former confirms the absence of antibodies against the deleted gene products after vaccination, although these antibodies are present after infection with the field strains of the pathogen. In the case of AIV, recombinant vaccines produce antibodies to the neuraminidase protein that is different from the field virus. PCR-based assays can also be used as in the case with the gE deletion mutant of bovine herpesvirus 1 (BoHV-1). In this test, a gE DNA fragment is amplified and analyzed by restriction enzymes (Schynts *et al.*, 1999). With the advance in new sequencing techniques, single-nucleotide polymorphism analysis could also be used in this example.

The possibility of deleting specific genes without significantly altering their immunogenicity was the basis for the first recombinant vaccine licensed in the United States. Deletion of two genes, Tk and glycoprotein III, in suid herpesvirus 1 (aka pseudorabies virus) led to the development of a marker vaccine that was successfully used to eradicate Aujeszky's disease in the commercial swine population in the United States in 2005 (USDA, 2008; Kit, 1990; CAST, 2008). Since then, several deletion and insertion techniques have been developed – mostly for herpesviruses and poxviruses but also for RNA viruses. The use of bacterial artificial chromosomes has increased the possibilities drastically by allowing the cloning of large DNA sequences, such as herpesvirus and poxvirus genomes and infectious cDNA (complementary DNA) clones of RNA viruses (Tischer and Kaufer, 2012). The use of *en passant* mutagenesis facilitates the deletion or mutagenesis of specific genes as well as the generation of vectored vaccines expressing foreign genes (Tischer *et al.*, 2010). Currently, several vaccines for chickens using fowlpox or HVT as a vector and expressing genes for AIV, infectious laryngotracheitis virus (ILTV), Newcastle disease virus (NDV), or infectious bursal disease virus (IBDV) have been licensed in the United States as well as in other parts of the world. There are currently no vectored vaccines for cattle and swine licensed in the United States (Anonymous, 2013c), but the gE deletion mutant of BoHV-1 has been licensed in the European Union for the control and

possible eradication of BoHV-1, which is the cause of infectious bovine rhinotracheitis.

In addition to poxvirus and HVT, NDV vaccine strains Lasota or B1 are also used as a vector for the expression of foreign genes, such as the HA gene of AIV (Park *et al.*, 2006). Recombinant NDV–HA vaccines are currently produced in Mexico. Adenoviruses have also been proposed as a vector for use in poultry and swine vaccines (Toro *et al.*, 2010) but are not yet available commercially.

Bacteria can also be used to generate apathogenic deletion mutants by removing pathogenicity genes. Curtiss and Hassan (Curtiss and Hassan, 1996) deleted genes for adenylate cyclase (*cya*) and cAMP receptor protein (*crp*) in *Salmonella enterica* serovar typhimurium (*Sa. typhimurium*) strain χ 3985. Vaccination of 1-day-old chicks generated significant antibody responses and booster vaccination at 16 or 18 weeks of age prevented egg transmission after challenge with highly invasive strains of *Sa. typhimurium* and *Sa. enterica* serovar enteritidis. The vaccine strain is currently licensed in the United States, Canada, New Zealand, and the Dominican Republic as AviPro Megan Vac 1 and AviPro Megan Egg (Lohmann Animal Health). This strain can also be used as a vector to immunize against other pathogens, especially when strong mucosal immunity is important; for example, to protect against *Eimeria acervulina* (Konjufca *et al.*, 2006). Since then several papers have been published showing protection against different pathogens after immunization with recombinant *Sa. typhimurium*, but it is not currently used commercially as a vector.

Subunit vaccines comprise the second group of biotechnology-derived vaccines and include proteins and VLP. Recombinant proteins and VLP can be produced by transfecting or infecting different cells, including *E. coli*, yeast, insect and mammalian cells. The choice of cells depends on a number of factors, such as posttranslational modifications, yield of protein, and purification methods. The platform of choice is currently the baculovirus system using insect cell lines or *Trichoplusia ni* (cabbage looper) larvae (Mena and Kamen, 2011; Crisci *et al.*, 2012). Recombinant protein vaccines that consist of the envelope glycoprotein E2 of classic swine fever (CSF) virus, a pestivirus, and produced in the baculovirus system have been licensed in Europe for the control of CSF. Vaccines that consist of recombinant proteins need to be injected and require adjuvants to induce strong immune responses. A problem with this type of vaccine is that the protein folding may not produce conformational (tridimensional) epitopes, which are often important for the production of relevant antibodies. This is not a problem if the antibodies are generated against linear epitopes.

VLP are self-forming virus-like structures lacking a virus genome that are generated when virus structural genes are expressed simultaneously (CAST, 2008). This can be achieved by infection of insect cell lines with recombinant baculoviruses expressing the structural genes. Crisci *et al.* (2012) listed several advantages for the use of VLPs: (1) the well-defined geometric structure with a highly repetitive expression of proteins on the surface presents PAMP motifs for triggering the immune response, (2) good cross-presentation to both MHC I and II by uptake by the APC resulting in CMI and antibody responses, (3) presents conformational epitopes, (4) is not infectious, and (5) can present foreign epitopes and can be used in DIVA strategies. One of the disadvantages of VLP vaccines prepared with the baculovirus system is that baculovirus particles that need to be removed can also be produced (Crisci *et al.*, 2012). Thus far only one VLP vaccine has been licensed for animals: Porcilis® PCV (Merck) for protection against PCV.

A slightly different approach has been used by Harrisvaccines (Ames, IA, USA) to generate RNA replicon vaccines for a H3N2 vaccine for swine. This vaccine has been licensed by the USDA (Anonymous, 2013c). The platform technology is based on alphavirus-derived nonstructural genes to which genes of interest can be fused. The construct is transfected into VERO cells, which then produce particles containing the recombinant RNA molecules. Although their website indicates that the method for particle production is proprietary, it is likely that these particles have the characteristics of VLP.

The finding that injection of mice with plasmid DNA encoding proteins resulted in expression of these proteins led to the concept that DNA could be used to immunize animals (reviewed by Dunham, 2002; Fowler and Barnett, 2012; CAST, 2008, and references therein). DNA vaccination is of interest because the DNA fragment codes only for part of the pathogen; thus, there is no risk that the pathogen escapes into the environment. The unmethylated CpG sequences in the DNA interacts with Toll-like receptors (TLR), thus enhancing innate responses. Interestingly, DNA vaccination sometimes induces strong CMI immune responses without the antibody responses, which complicates monitoring if appropriate levels of protection have been achieved. The proposed mechanism for the induction of both types of immune responses is that APC are directly stimulated by transfection of the plasmid into the APC or by proteins expressed in transfected somatic cells. Although DNA vaccines have attracted strong interest for their potential use in humans, the development of vaccines for production animals has been lacking with one exception. A DNA vaccine to protect salmonids against infectious hematopoietic necrosis virus has been licensed in Canada (Alonso and Leong, 2013) (see Section Vaccines for Fish). One of the problems is that injection of plasmids into the muscle or dermis does not always result in adequate responses without the addition of an immunogenic protein and or cytokines or unless multiple injections are given. The use of a gene gun administering gold particles coated with DNA has improved the results probably by delivering the vaccine into the epidermis, which is rich in professional APC (keratinocytes and Langerhans cells) (Fuller *et al.*, 2006).

Adjuvants

Killed vaccines, including recombinant protein vaccines, are frequently used with adjuvants to increase the immunogenicity. Most of the adjuvants used in vaccines for production animals and humans consist of aluminum- or oil-based emulsions (reviewed in Fox and Haensler, 2013; Schijns and Lavelle, 2011; Schijns *et al.*, 2014). Mineral oil or natural oils together with surfactants are used to prepare the oil-based emulsions. Squalene, a naturally occurring substance in plants and animals, including humans, has replaced mineral oil-based formulations in human vaccines (Fox and Haensler, 2013). Final compositions of adjuvants are frequently proprietary information and in animal vaccines are based in part

on price considerations, in addition to immunostimulatory properties.

Although the use of adjuvants has a long history, the actual mechanisms involved are still poorly understood (reviewed in Schijns and Lavelle, 2011; Schijns *et al.*, 2014; Mount *et al.*, 2013). The aluminum- and oil-based adjuvants remain present for some time after vaccination, providing a depot function for antigen release, which has been named signal 1 facilitators. However, the depot also causes tissue damage, thus facilitating an inflammatory response (signal 2 facilitators). The former results in gradual release of the antigen to macrophages and APC, whereas the latter activates the innate immune response pathway by providing ligands to PRR, such as TLR (see Section Relevant Immune Responses). The use of adjuvants in production animals can cause economic problems if the resulting tissue damage decreases the value of the product (see Section Selected Examples of Vaccines in the Four Groups of Production Animals).

Based on the current understanding of the initiation of innate immune responses, research to develop new and improved adjuvants stimulating CMI and antibody responses is being conducted (e.g., Mount *et al.*, 2013). Most of this research is directed toward the development of adjuvants for human vaccines. Incorporation of new adjuvants into vaccines for production animals will only be done if it provides economic value, for example, by less damage to meat products.

Vaccination Procedures

To obtain optimal protection, vaccines must be administered using the correct procedures as outlined by the manufacturers. Unfortunately, these recommendations are not always followed, especially if vaccines are provided by other methods than injection. In the case of cattle and swine, vaccines are mostly administered by subcutaneous (sc), intradermal, or intramuscular (im) injection. The location of injection may depend on the preference of the veterinarian and the owner of the animals. Some vaccines can be given intranasally, such as the recombinant vaccine against BoHV-1 (Schynts *et al.*, 1999) in cattle or deletion mutant vaccines for Aujeszky's disease in swine, but this may not always be practical. Oral vaccination can be used for some of the bacterial vaccines in swine by adding the vaccine to the drinking water. Aerosol vaccination to protect piglets against *Mycoplasma hyopneumoniae* is possible (Murphy *et al.*, 1993; Feng *et al.*, 2013), but it is not clear whether this is currently used.

Poultry vaccines can be given by *in ovo* injection or in chickens by spray, intraocular or eye drop, in the drinking water, wing-web stab, or by sc or im injection. In this article the author has briefly reviewed these different techniques: detailed information on the advantages and disadvantages has been discussed by Collett (2013). The concept of *in ovo* vaccination was developed by Sharma and Burmester (1982) for the HVT Marek's disease vaccine. The development of machines for *in ovo* vaccination was pioneered by Embrex (now Zoetis) and is widely used to vaccinate broiler embryos. Current machines can vaccinate up to 70 000 eggs h^{-1} and at the same time remove infertile eggs and eggs with embryos that died within the first 10 days of incubation (**Figure 3**). The mechanisms involved in early protection are not completely understood but probably involve early activation of innate immune responses and, if the machine is properly calibrated,

Figure 3 An automated *in ovo* vaccination device shown with an egg candling module and a capacity to inoculate up to 70 000 eggs h^{-1}. At approximately 18 days of incubation the flats with eggs are loaded on an egg remover module (right front) where infertile eggs and eggs with dead embryos are removed, thereby reducing chances of contamination. The flats are then moved to the next module for vaccine injection/delivery through a multiple-head, injector assembly that consists of a punch and needle system. After injection, the flats are moved to the transfer table module where eggs are automatically transferred to hatching baskets to be moved into the hatching incubator. Photo of the Embrex® systems (Inovoject® vaccination device with Vaccine Saver® feature and egg remover module) courtesy of Zoetis Inc.

approximately 100% of the embryos will receive the correct vaccine dose. This is in contrast with vaccination of newly hatched chicks at the hatchery by sc injection, where chicks are often not at all or improperly vaccinated. One-day-old chicks are vaccinated before leaving the hatchery by sc injection, spray, and ocular or nasal drop. Spray vaccination at the hatchery is done in a cabinet where the boxes with chicks receive the spray. At the farm, spray vaccination is often employed for respiratory vaccines using adaptations of insecticide spray equipment. Droplet size is crucial in both situations with 100–150 μm being optimal. Smaller droplets may cause undesirable vaccine reactions. The labor-intensive eye or nasal drop vaccination is probably not used in many countries due to labor costs, although it is used in countries like India at the farm level instead of spray vaccination. Vaccination by drinking water is effective but requires proper preparation of the equipment and birds. Flushing the system to remove all disinfectants is important and if the only water supply is chlorinated water it will not work at all. Before vaccinating, water must be withheld from the birds so that they drink as soon as water becomes available. Proper preparation of the vaccine solution is done by adding buffers to the drinking water (e.g., skim milk), which needs to be well mixed with the vaccine. Improper application of any of the vaccination techniques can cause disastrous results.

Vaccination of fish has become very important in aquaculture. Originally, it was thought that this could be done by immersion of fish in a tank with vaccine. However, this required large concentrations of vaccine, which made this method prohibitively expensive. Moreover, protective immunity was not uniformly achieved by this method. Currently, vaccination is done by intraperitoneal injection in almost all instances (Rødseth and Moen, personal communication). Fish are placed briefly in an anesthetic solution before being injected manually (**Figures 4(a)** and **(b)**). The Norwegian company Skala Maskon has developed a machine that can vaccinate 20 000 salmon h^{-1} and separate the fish into different weight classes while rejecting malformed fish (**Figure 5**). In some countries oral vaccination is used by encapsulating the vaccine in different components (reviewed by Gomez-Casado *et al.*, 2011).

Selected Examples of Vaccines in the Four Groups of Production Animals

In this section, the author has highlighted some of the specific aspects for each group of animals focusing on diseases of global interest. It is not possible to provide detailed vaccination schemes for production animals for several reasons. First of all, it is almost impossible to obtain reliable information on regional disease incidence and vaccine use. Two examples illustrate the geographic differences in vaccine use. The United States has been free of FMD virus (FMDV) since 1929 (McReynolds and Sanderson, 2014), whereas FMDV is still endemic in large parts of Asia. Similar examples can be given for the poultry industry in regard to H5N1 highly pathogenic (HP)AIV. Several countries in Asia and Egypt routinely vaccinate against the H5N1 AIV, whereas countries in Europe may use stamping out; however, the United States is free of HPAIV. Decisions on how to deal with these two diseases are determined by the national governments or the European Union.

The second reason is that veterinarians working for poultry producers often have to follow vaccination schemes that are implemented by the veterinary staff at the headquarters of large producers. These vaccination schedules can be based on regional differences in disease incidence, density of poultry farms in a given region, etc. This situation is very similar to that of the aquaculture industry. The list of bovine vaccines (**Table 3**, **Figure 6**) that are currently used in the United States is provided only to demonstrate the type of vaccines that are available, although these vaccines are not always used. Additional information on vaccines and their regional use can be obtained by accessing websites of the large vaccine manufacturers and government licensing agencies. Different articles in this Encyclopedia deal with descriptions of the common diseases in the four groups of food animals and the interested reader may refer to those articles for additional information.

Vaccines for Cattle

Cattle receive many vaccinations starting after 3 months of age when maternal immunity no longer interferes with vaccination by neutralizing the vaccine virus. **Table 3** provides an example

(a) (b)

Figure 4 (a) Manual vaccination of Atlantic salmon by intraperitonal injection. (b) Manual mass vaccination of Atlantic salmon performed by a professional team of vaccinators. Photos: MSD Animal Health.

Figure 5 A vaccination system for intraperitoneal injection of salmon. Fish enter in the Maskon anesthetizer and buffer tank (not shown) and are transported to the vaccination unit, which has injection sites. Location of the injection site and needle depth is adjusted for every fish based on the length of the fish. The unit is operated by one person and depending on the configuration, up to 20 000 fish can be vaccinated per hour.

Table 3 Vaccines for cattle available in the United States

Viruses	*Bacteria*	*Protozoa*
Infectious Bovine Rhinotracheitis (IBR)	Leptospira	*Neospora*
Bovine Viral Diarrhea (BVD)	Clostridia	Trichomoniasis
Bovine Respiratory Syncytial Virus (BRSV)	*Pasteurella* (Mannheimia)	
Parainfluenza (PI3)	Brucellosis	
Rotavirus	Vibriosis	
Coronavirus	Enteric *E. coli*	
Rabies	*Salmonella*	
Papilloma	Gram-negative core bacterins	
	Footrot	
	Hemophilus	
	Anthrax	
	Staphylococcus aureus

of the types of vaccines available in the United States, whereas Figure 6 indicates the frequency of the use of the different vaccines (Data for 2007, provided by Professor L. Warnick, Department of Population Medicine and Diagnostic Sciences, Cornell University). It is noteworthy that the use of *Brucella* vaccines is different in the western part compared with the eastern part of the United States. This is most likely the consequence of the presence of *Brucella abortus* in free-living bison (*Bison bison*) and elk (*Cervus canadensis*) (Olsen, 2013) combined with the extensive ranching of cattle in the western half of the United States.

The following diseases are of global interest for which vaccines are available and are briefly discussed: mastitis, a major worldwide economic disease in dairy cattle; brucellosis is a major zoonotic disease, caused by *Brucella abortus* and a potential bioterrorism agent; and FMD.

Mastitis is an infection of the udder frequently caused by intramammary infection with *Staphylococcus aureus* (*St. aureus*) or different coliforms (e.g., *E. coli*, *Klebsiella* spp, and *Enterobacter* spp). The host response and pathogenesis of bacterial intramammary infections have recently been reviewed (Schukken *et al.*, 2011) and the interested reader may refer to this article for additional information. Production losses are caused by clinical mastitis, an obvious disease state, or subclinical mastitis when the somatic cell count (mostly leukocytes and some epithelial cells) is increased above 100 000 ml^{-1} of milk. Prevention of mastitis is primarily based on sound management practices and vaccination is considered an adjunct to the overall herd health management programs (Erskine, 2012). Vaccines against coliforms consist of Gram-negative 'core antigen' bacterins, referred to as GNCABs, using the Rc mutant strain O111:B4 of *E. coli*.

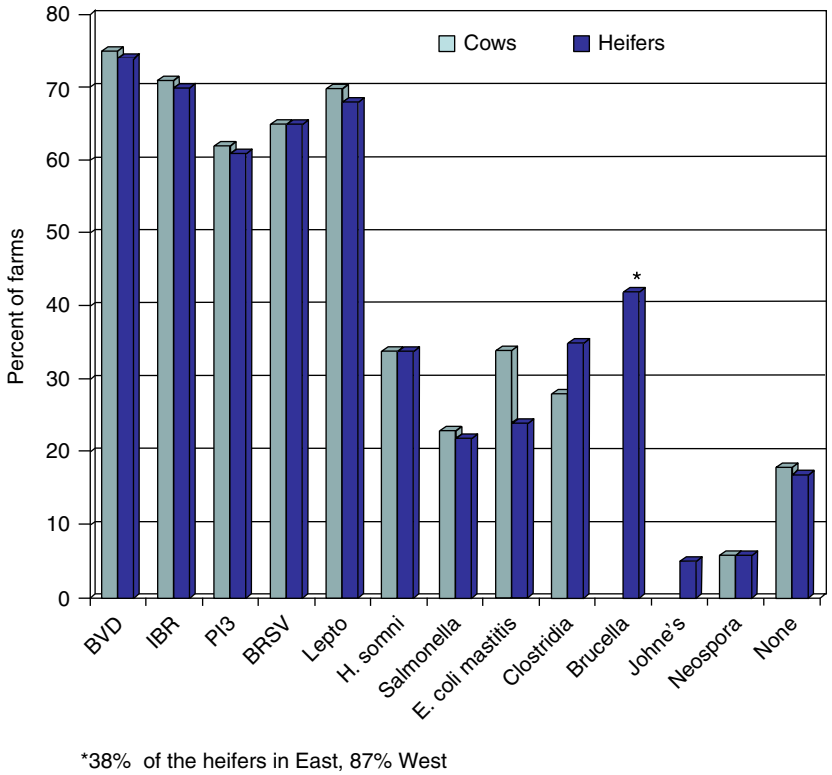

Figure 6 Graphical representation of the use of different vaccines for cattle in the United States. Note the difference in use of *Brucella abortus* vaccine between the eastern and the western half of the United States. Courtesy of Warnick, L.D., Department of Population Medicine and Diagnostic Sciences, Cornell University.

Vaccination with this vaccine, referred to as J5, provides moderate protection against coliforms. More problematic is the control of *St. aureus* mastitis by vaccination. Pereira et al. (2011) and Erskine (2012) reviewed the literature on *St. aureus* vaccines and found mixed results for the current commercial vaccines. New vaccine formulations using recombinant Target of RNAIII-Activating Protein (TRAP) (Leitner *et al.*, 2011) and ISCOMATRIX™ (Camussone *et al.*, 2013) show promising results for improved protection.

Brucella abortus, a Gram-negative intracellular bacterium, causes abortion and other reproductive diseases in cattle. Infection with *B. abortus* induces rather poor immunity because it can subvert innate and acquired responses. Vaccination using live attenuated strains (strain19 is most commonly used) together with elimination of positive animals is the preferred strategy. However, the currently available vaccine strains have some serious drawbacks. Vaccination can induce abortions in pregnant animals and does not prevent superinfection and seroconversion. Vaccinations need to be conducted with great care, because the vaccine strains can also cause infection in humans (Olsen, 2013).

Control of FMD by vaccination is complicated for several reasons (Parida, 2009). First of all, vaccine-induced protection lasts for the relatively short period of approximately 6 months; thus, yearly vaccinations are essential in endemic parts of the world. Second, there are at least seven distinct serotypes with considerable antigenic diversity within serotypes. As a consequence, vaccine formulations need to be carefully evaluated for efficacy, which is difficult to achieve. Challenge experiments for such evaluations require strict isolation facilities to prevent outbreaks. Third, current inactivated FMD vaccines require a cold chain, which is also a complicating factor, especially in tropical regions, impeding efficient immunizations.

In many parts of the world, tick-borne diseases are important in cattle with control often done by pushing the cattle into dip tanks that contain acaricides. The use of a recombinant vaccine based on gut glycoprotein BM86 of the *Rhipicephalus microplus* tick has been successfully used in Australia and Latin American countries (de la Fuente *et al.*, 2007). Unfortunately, the BM86 vaccine has limited activity against non-*Rhipicephalus* ticks, but it is likely that new candidate vaccine antigens will be discovered in the near future (de la Fuente and Merino, 2013).

Vaccines for Swine

The intensive swine industry uses several production systems, but all consist of farrowing, nursery, growing, and finishing units, with the latter two frequently combined into one unit. On some farms, all units are used in a continuous production system, preventing the use of an all-in/all-out system and thorough cleaning of the facilities. Other systems use fully separated facilities and the grower/finishing units may be completely different farms than the farrowing/nursery farms. Piglets are moved to nursery units after weaning at approximately 3 weeks of age, which is also the prime time for vaccinations by injection. In some instances a booster vaccination is given at 6 weeks of age. Sows can be vaccinated between

2 and 5 weeks before farrowing to increase antibodies in the colostrum. Although most vaccines are given by injection, attenuated live strains of bacteria (*Lawsonia intracellularis* causing ileitis and *Salmonella* and *E. coli* causing diarrhea) can be given in the drinking water. Over the past 20 years, two important new diseases have appeared worldwide in swine: PCV serotype 2 (PCV2) causing immunosuppression and wasting pigs, and porcine reproductive and respiratory syndrome (PRRS) caused by Arterivirus. Recombinant vaccines have been developed against PCV2 using VLP (Merck), a recombinant protein produced in a baculovirus system (Boehringer Ingelheim) or a recombinant hybrid inserting the VP2 gene of PCV2 into the genome of the nonpathogenic PCV serotype 1 virus (Zoetis). The latter is the only live vaccine against PCV2. Development of vaccines against PRRS is problematic for several reasons (Cruz *et al.*, 2010). Natural infection or attenuated vaccines induce weak innate immune responses and low levels of VN antibodies and virus-specific CTL. Moreover, PRRSV strains are highly diverse, especially for the immunodominant protein GP5. It is also suggested that CTL responses are more important for protective immunity than VN antibodies. Development of recombinant vaccines inducing strong CTL responses may solve the shortcomings of the current vaccines. Cruz *et al.* (2010) used a vectored vaccine with transmissible gastroenteritis virus as the backbone expressing two PRRSV antigens eliciting strong VN antibody and CTL responses as well as good mucosal immunity. Currently, this type of recombinant vaccine has not been licensed.

Vaccines for Poultry

Regional and national differences in prevalence of specific poultry diseases are well recognized. As a consequence, decisions on the selection of vaccines are frequently made by the veterinary staff of large integrated companies based on the regional needs and national policies. It is, therefore, not possible to provide detailed information on all poultry vaccines used in the world and hence only some general concepts are discussed.

Vaccination schedules depend on the type of bird; the needs for vaccination of grandparent and parent flocks are different than those for commercial layers and broilers. Because maternal antibodies are important for the protection of chicks, (grand) parent flocks are frequently vaccinated with a live vaccine to prime the immune response followed by a killed adjuvanted vaccine before lay to boost the antibody titers. Boosting with a live vaccine is not recommended because the neutralizing antibodies produced by the first vaccination interfere with vaccine virus replication from the booster vaccination.

The use of recombinant vectored vaccines has become a common practice in many parts of the world, mostly using HVT as the vector. Interestingly, HVT-vectored vaccines cannot be used together with conventional HVT, nor can different recombinant vaccines be used at the same time (e.g., HVT–IBD and HVT–NDV) unless the two inserts are present in the same vector. Possible explanations are that the insert negatively influences the replication rate of the vectored vaccine in the bird with the consequence that conventional HVT initiates immune responses before the recombinant HVT, thus curtailing the infection of the latter. The second explanation could be that the vectored vaccine has a higher passage level *in vitro* and therefore replicates slower in the bird with the same consequences. Similar circumstances may explain the recommendation against using two different recombinant HVT vaccines. The consequence of using recombinant HVT instead of the standard HVT is that protection against MD may be suboptimal and therefore protection to MD depends more on the inclusion of SB-1 and or CVI988 (aka as Rispens). The slower replication of, for example, recombinant HVT expressing VP2 of IBDV may still protect against IBD because maternal antibodies will provide sufficient protection against IBD during the first 14 days after hatching.

Vaccination against AIV provides a challenge, especially since the occurrence of highly pathogenic H5N1 AIV. Some countries do not allow vaccination, whereas others use killed adjuvanted vaccines. AIV, a member of the orthomyxoviridae, has a genome that consists of eight different RNA molecules, one of which codes for the hemagglutinin (H) protein and a second one for the neuraminidase (N) protein. Chickens make antibodies against both proteins, but the antibodies against H are the key for neutralizing the virus. By changing the N gene to a different neuraminidase gene (e.g., N2 in the case of a vaccine against H5N1), it is possible to monitor flocks for field exposure to H5N1. Recombinant vaccines expressing a different N protein than the field virus have successfully been used in Italy during outbreaks of avian influenza (Capua *et al.*, 2003).

Vaccines for Fish

Globally, approximately 600 fish species are farmed (Brudeseth *et al.*, 2013), but only a few species are produced at high densities, such as salmonids. Vaccine development has become an integral part of aquaculture management for these species and several review papers have summarized the availability of vaccines against viral and bacterial diseases (Gomez-Casado *et al.*, 2011; Salgado-Miranda *et al.*, 2013; Brudeseth *et al.*, 2013). One of the problems identified in these papers relates to the fact that almost all vaccines consist of water-in-oil emulsions that need to be injected. The adjuvants in the vaccine can cause adhesions in the peritoneal cavity, which negatively influences the quality of the fish meat. To reduce the impact of adjuvants on the meat quality, multivalent vaccines that contain antigens against different pathogens are frequently used. The type of combinations depends on the geographic locations (Brudeseth *et al.*, 2013). The other major problem is that a number of viral diseases can cause high mortality in swim-up fry. Unfortunately, the very young fish have an immature immune system, are too small to be injected, and maternal immunity is not very effective in fish (see Section Maternal Immunity). Live, attenuated vaccine strains cannot be used mainly because attenuation in one fish species does not translate to attenuation in other fish species. Vaccination by immersion is in general not cost effective, although it is used with some bacterins in channel catfish and salmonids (e.g., *Yersinia ruckeri* bacterin).

As mentioned in the Section 'Vaccination Procedures,' DNA vaccines for IHNV are licensed in Canada. IM inoculation of plasmid DNA that contain the IHNV glycoprotein G gene provides long-term protection against challenge without causing long-term lesions at the site of inoculation (Kurath *et al.*, 2006). Protective immunity is likely achieved by

a combination of VN antibodies, CTL, and NK cells based on studies in rainbow trout (*Oncorhunchus mykiss*) (Utke *et al.*, 2008). Interestingly, vaccination with plasmid DNA for IHNV glycoprotein G induced not only rapid protection against challenge with IHNV but also cross-protection against another rhabdovirus (viral hemorrhagic septicemia virus) infection for the first 2 months postvaccination (Lorenzen *et al.*, 2002). An experimental DNA vaccine expressing VP2 of IPNV encapsulated in alginate microspheres showed good protection against challenge 15 and 30 days after oral vaccination (de las Heras *et al.*, 2010). It is expected that DNA vaccines will become an important part of fish health management if oral vaccination works in general and if safety concerns can be overcome.

Conclusions

Vaccines remain an important part of health management programs in food animal production systems. It is expected that progress will be made over the next 5 years toward safe vaccines using different recombinant technologies. The use of vectored live vaccines in poultry and DNA vaccines in fish has shown that these applications are safe and provide strong protection. Research into the mechanisms of adjuvants will also lead to the development of science-based approaches stimulating innate and acquired immune responses.

Acknowledgments

This article would not have been possible without the assistance of many colleagues. Cornell faculty members Drs Dwight Bowman, James Casey, Cynthia Leifer, Kathy Earnest-Koons, Debbie Dorothy, and Lorin Warnick provided crucial information and feedback on selected topics. The following colleagues outside of Cornell provided information and photographs in a timely fashion, which was much appreciated: Drs Nikki Pritchard (Merial), Steven Olsen (APHIS-USDA), Odd Magne Rødseth and Thomas Moen (Aquagen), Rebecca Poston, Nimish Tolat and Jim Allison (Zoetis), Daniel Windhorst (Lohman Animal Health), Roy Curtiss III (Arizona State University), Irene Nygaard (MSD Animal Health), Jim McKay (EW group), Rune Reinås (Skala Maskon, NO), and Ynte Schukken (Gezondheidsdienst voor Dieren, NL). Finally, the author is much indebted to Laura Stenzler for editing the manuscript.

Virtual Water and Water Footprint of Food Production and Processing

WEL Spiess, International Academy of Food Science and Technology, Oakville, ON, Canada, and Karlsruhe Institut für Technologie (KIT), Karlsruhe, Germany

© 2014 Elsevier Inc. All rights reserved.

Glossary

Blue water The ground- and surface water; it is the fraction of water which is available as drinking water, process water, water for irrigation in agriculture; it is used as a transport medium and many other purposes.

Evapotranspiration The sum of water evaporation and plant transpiration from the earth's land surface into the atmosphere.

Gray water The volume of freshwater that is required to assimilate the load of pollutants based on existing ambient water quality standards.

Green water The water which is bound in the soil and in green plants; it is under normal circumstances the basis for agricultural production.

Virtual water The amount of water needed for the production and handling of any type of product, for example, food; it is also referred to as hidden water.

The Origin of Water on Earth

Water (H_2O) is not only one of the most common molecules on the surface of the earth but it is also one of the most abundant molecules in the universe, where it originated within the clouds of interstellar media as a chemical compound of hydrogen and oxygen. It is not entirely clear where the Earth got its water from, but it can be assumed that water was part of the protoplanetary material from which the planets were formed. Some of this water was released during the formation of the Earth, and it is understood that there is still a major amount of water entrapped in the Earth's crust and mantle. Through volcanic activity, annually up to one-tenth cubic kilometer of juvenile water is expelled as overheated steam or as part of the magma, which may have a water content of 5% by weight, according to certain assumptions. A significant part of the water on earth may also have been contributed by icy comets which smashed into the young earth (Müller and Lesch, 2003; Shiklomanov, 1993).

Distribution of Water on Earth

Water on Earth is unevenly distributed in the Northern Hemisphere, where the world's oceans occupy 61% of the area and in the Southern Hemisphere 81%. On the so called water-sphere of the globe, approximately 89% of the surface is covered by water, and on the land-sphere 43% of the surface is covered by water; all together, 71% of the Earth's surface is covered by water, as depicted in **Figure 1**.

The total water resources on earth are approximately 1.4 billion km^3; the volume of freshwater resources is approximately 35 million km^3; this means that approximately 2.5% of the total volume is freshwater. Of the freshwater resources, approximately 24 million km^3 or 68.7% is permanently affixed in the form of ice and permanent snow cover in mountainous regions and the Antarctic and Arctic regions. Some 10.4 million km^3, i.e., 29.9% of the freshwater pool is stored underground as groundwater; soil moisture, permafrost areas, and swamps bind approximately 0.4 million km^3, or 1.14%; that leaves approximately 0.09 million km^3 of freshwater, or approximately 0.26% of the world's freshwater available for human use; that means only a minute fraction of the global water resources are accessible for economic needs. It should be noted at this point that there are slightly different reference data presented in the literature (**Table 1**; Pidwirny, 2006).

The Global Water Cycle

Energized by solar radiation, water evaporates and sublimates from open water, snow, and ice surfaces, as well as from all humid surfaces with a water vapor pressure and from plants transpiring into the atmosphere. It is estimated that the atmosphere contains a buffer of approximately 13 000 km^3 of water as vapor or in a condensed state. When the dew point of the water vapor in the atmosphere is passed, water precipitates as rain or snow. Globally all forms of precipitation are in equilibrium with all forms of evaporation and sublimation.

On a long-term average, rainfall on the land surface amounts to approximately 110 000 $km^3\ year^{-1}$; of this quantity, approximately 70 000 $km^3\ year^{-1}$ evaporates again into the atmosphere and approximately 40 000 $km^3\ year^{-1}$ runs off into the oceans to cover, together with a groundwater flow into the oceans, the oceans' net evaporation losses. These losses arise from the fact that the amount of evaporation from the ocean surface exceeds the amount of precipitation directly onto the oceans (Zehnder, 2002; **Figure 2**).

The residence times of the various water fractions differ considerably. The fastest turnover occurs in the atmosphere, where water is replaced every 8 days. Water in rivers is on average renewed every 16 days. Residence times in bodies of stagnant water and ice vary considerably, between several months to thousands or millions of years (**Table 2**).

The global water cycle is of primary importance for the hydrologic inventory. Through the evaporation of sea water and land surface water, a permanent supply of 'clean,' purified water is generated; this flux of water may contain different kind of aerosols when it precipitates. Because of the high specific heat and the high condensation/evaporation heat, evaporation and precipitation processes have also a pronounced impact on the global weather.

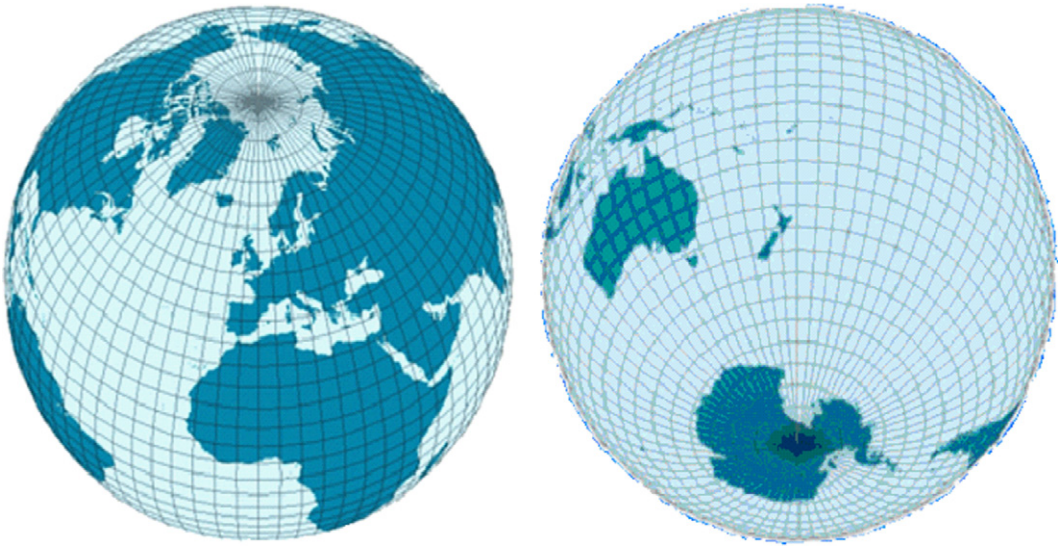

Figure 1 The land and the water sphere.

Table 1 Global water resources

Global water resources					
Approximately 1.4 billion km³ (1.386 billion km³)					
Sea (salt) water		*Freshwater*			
97.5%	*1.351 4 billion km³*	*2.5%*	*0.034 7 billion km³*		
Sea water composition		*Type of freshwater*	*Global water resources (%)*	*Freshwater resources (%)*	*Amount (in billion km³)*
Contributing to sea water salinity	Concentration in o/oo (parts per thousand) in average sea water	Glaciers and permanent snow	1.717 5	68.7	0.023 8
		Groundwater	0.747 5	29.9	0.010 4
		Soil moisture, swamps and permafrost	0.028 5	1.14	0.000 4
Chloride	19.345				
Sodium	10.752	Lakes and rivers (only water share)	0.006 5	0.26	0.000 09
Sulfate	2.701				
Magnesium	1.295	Utilization of renewable fresh water resources			
Calcium	0.416				
Potassium	0.390	Irrigation: 70%			
		Industry: 22%			
		Domestic use: 8% (12.500 km³)			
According to Castro and Huber, 2012					
		Total	2.5	100	0.034 7

The precipitation as rain or snow is not evenly distributed on the earth's surface; nor is it evenly distributed over the year. Areas with high precipitations are located between the equator and the 30th degree of southern latitude. Examples of seasons with high precipitations are the West African and Asian-Australian monsoons. Besides zones of high precipitation, zones with almost no precipitation stretch mainly from the equator to 30° N; zones of moderate precipitation are mainly above 30° N (**Figures 3** and **4**).

It is anticipated that with rising environmental temperatures in future years, more areas around the globe will experience droughts, especially in the Americas, Southern Africa, the Middle East, and Australia.

High precipitation rates such as monsoons, however, as well as cases of sudden snowmelt, frequently cause major floods; the runoff of floodwater into the ocean may consist of 75% (30 000 $km^3\ year^{-1}$) of the water flux into the oceans. Heavy rainfalls and floodwater runoff are of significant

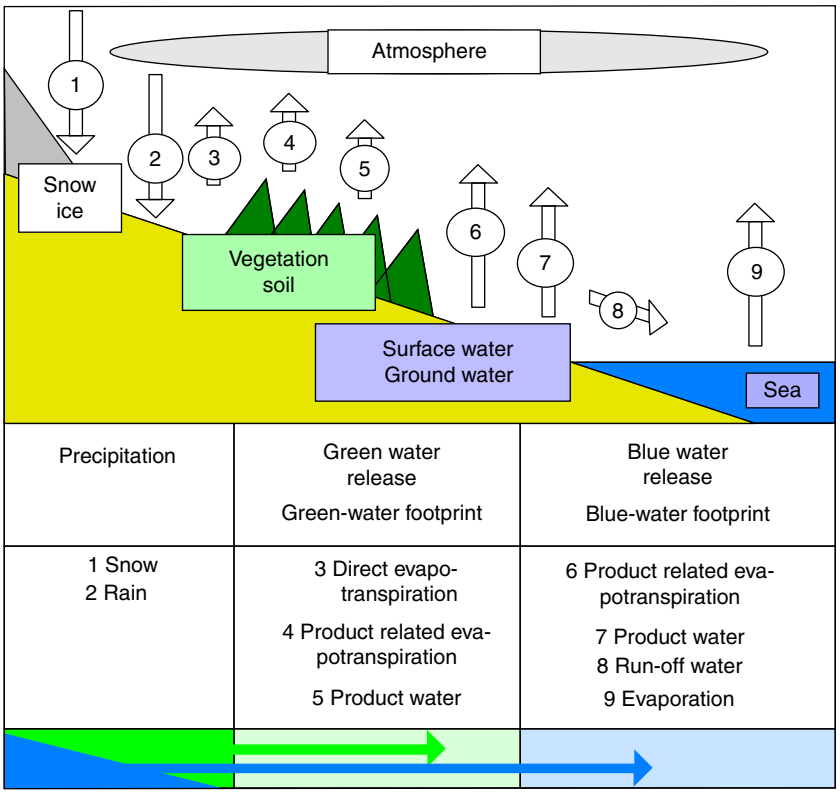

Figure 2 The water cycle.

Table 2 Typical residence times of water found in various reservoirs

Reservoir	*Residence time*
Oceans	3000–3230 years
Glaciers	20–100 years
(Antarctic glaciers)	Millions of years (Ingólfsson, 2004)
Seasonal snow cover	2–6 months
Soil moisture	1–2 months
Groundwater: shallow	100–200 years
Groundwater: deep	10 000 years
Lakes	50–100 years
Rivers	2–6 months
Atmosphere	9 days

importance for the desalination of the soil and cleaning of contaminated water systems.

Physical Properties of Water Related to Food Processing

Water is the only substance that occurs in large amounts in all three physical states on earth and in the atmosphere. It is present as vapor, ice (particles), as a liquid (rain drops) in the atmosphere, in liquid form as surface water, and in various forms as underground water, as well as snow and ice in the polar and alpine regions of the globe. It is frequently overlooked that water also can be found in the supercritical phase in volcanic vents.

A water molecule consists of one oxygen and two hydrogen atoms connected by covalent bonds. Because of the nonlinear structure and the fact that the oxygen atom has a higher electronegativity than the hydrogen atoms, and the hydrogen atoms are slightly positive, water is a polar molecule with an electrical dipole moment. Because of the electrical properties of its molecule, water usually forms large molecule clusters and exhibits special physical properties including high surface tension and capillary forces. A schematic orbital model is given in Figure 5.

Through its unique physical-chemical properties, water is one of the substances on which life on earth depends; without water life on earth would not exist in its present form. In nature, water acts as a solvent, as a carrier of nutrients and metabolites, as a catalyst of reactions, as a stabilizer of biopolymers, as a plasticizer, and many other reactions. Because of its properties as a solvent, water can hardly be found as a pure substance. Water is the major component of almost all living species, including food materials, with an average water content of approximately 80%±10% of the total weight. Water determines the properties of the food materials, their structure, appearance, taste, and stability, and, in the end, the ways in which a product can be processed. The rather low viscosity and high surface tension of water allow for fast flows and for storage of major amounts in porous systems like soil (for details on these physical properties see Tables 3 and 4 and Figure 6).

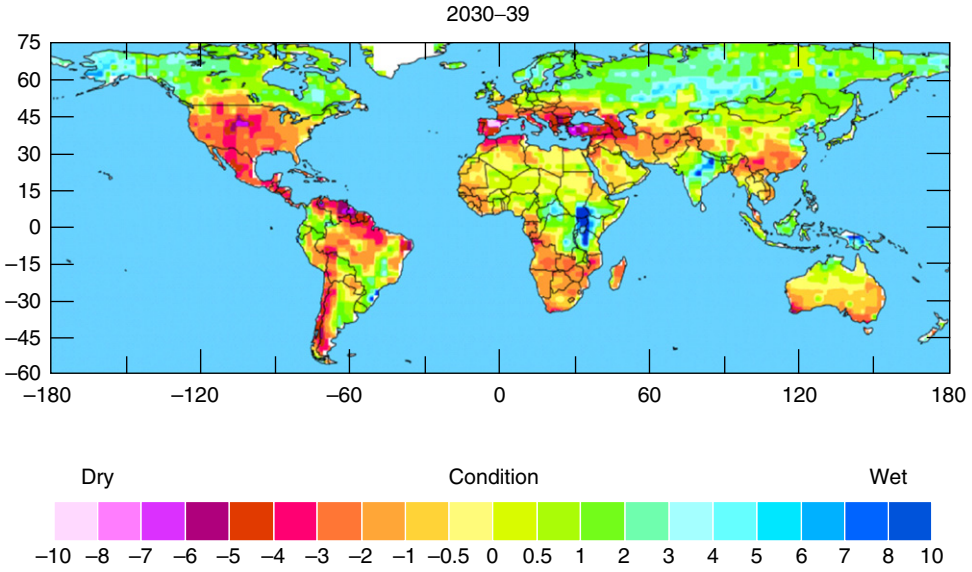

Figure 4 Predicted global distribution of rainfall in the decade 2030–39. Reproduced from Dai, A., 2010. Drought Under Global Warming: A Review. Available at: http://www2.ucar.edu/atmosnews/news/2904/climate-change-drought-may-threaten-much-globe-within-decades#mediaterms (accessed 29.01.14).

The Virtual Water and the Water Footprint Concept with Regard to Food Production, Processing, and Distribution

Global Water Availability and Water Consumption

Precipitation of water is not evenly distributed over the globe, as mentioned above (see Figure 4); major amounts of precipitation are released over areas where they cannot be utilized for food production and other human needs. To satisfy the needs of populations with water shortages, or more precisely with an insufficient water supply for the production of an adequate food supply, export and import of goods relying on the presence of water for their production is the consequence.

To make things more complicated, the distribution of water resources does not correspond to the distribution of the world's population (Table 5).

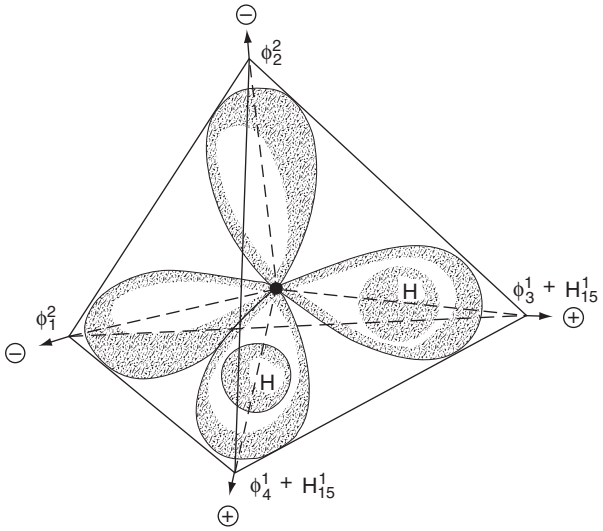

Figure 5 Schematic orbital model of a water molecule. Reproduced from Spiess, W.E.L., 2002/2003. Chilling and Freezing: An Introduction Chilling and Freezing to Food, Lectures on Freezing of Food Materials. Seoul National University.

Table 3 Physical properties of water

Physical properties of water	
General properties	
Molecular formula	H_2O
Molar mass	18.015 28(33) g mol^{-1}
Density	1000 kg m^{-3}, liquid (4 °C) 917 kg m^{-3}, solid
Melting point	0 °C
Boiling point	99.98 °C
Acidity (pK_a)	15.74 ~35–36
Basicity (pK_b)	15.74
Refractive index (n_D)	1.333 0
Viscosity	0.001 Pa s at 20 °C
pH	7 at 25 °C
Surface tension	72.8 mN m^{-1}
Dielectric constant ε	(0 °C) 87.9; (50 °C) 69.88; and (100 °C) 55.58
Heat capacity C_p	(0 °C) 4.2; (20 °C) 4.18; and (100 °C) 4.22 J $(g\ K)^{-1}$ at 100 kPa
Heats of vaporization H_v	(100 °C) 2256 kJ kg^{-1}
Heats of fusion H_f	(0 °C) 333.55 kJ kg^{-1}
Dissociation constant K_w	(25 °C) 10^{-14}
Thermal conductivity λ	Liquid water (0 °C) 0.56 W $(m\ K)^{-1}$; Ice (0 °C) 2.18 W $(m\ K)^{-1}$;
Dielectric constant ($e_r = e/e_0$)	81.1 (18 °C)
Vapor pressure	
Temperature (°C)	Pressure/Pa
0	611
12	1403
25	3168

Currently, approximately 4000 km^3 of freshwater are withdrawn annually from the various resources. The main sectors of water consumption are agriculture, industry, and private households; also in addition, recreation and the environment take a share. On a global average, approximately 70% of the amount withdrawn from water resources is used for agriculture, 20% for industrial purposes, and 10% for the domestic sector, mainly private households. It is estimated that the agricultural sector benefits in addition from a direct water supply through rain on agricultural production sites, on the order of 6400 $km^3\ annum^{-1}$. The share of the industrial sector may vary considerably from country to country; for example, according to Food and Agriculture Organization (FAO) data, North America and Europe use up to 50% of the water withdrawn from the available resources.

Main industrial consumers are thermoelectric power plants, ore and oil refineries, the chemical industry, and other industrial branches. In the highly developed industrial countries, water used as an intermediate process aid is usually released in high quality (drinking water quality) and can be easily reused.

The hotspots of the various types of consumption are also not equally distributed over the globe; most of the water for agriculture production is used at latitudes south of 30 °N, whereas water for various industrial purposes is mainly used above this line. Water for domestic use is almost evenly spread around the globe (Figures 7 and 8).

Under extreme threat of water shortage is Asia, with close to two-thirds of the world population and less than one-third of the worlds water resources; according to FAO data, the most populous countries on the globe withdraw together almost one-third of the entire amount withdrawn, despite the fact that the per capita consumption in these countries is rather low. Further, the top consumers are the US, Pakistan, Iran, Japan, Thailand, Indonesia, and Bangladesh. Especially difficult is the situation in Africa, because of an extremely underdeveloped infrastructure for distributing scarce water resources.

Globally, per capita water withdrawal varies between major consumers, for example, the cotton producing countries in Central Asia, and countries with an extremely small consumption in Central Africa; highly industrialized countries and countries with a medium-sized agricultural sector occupy the middle ground (Table 6).

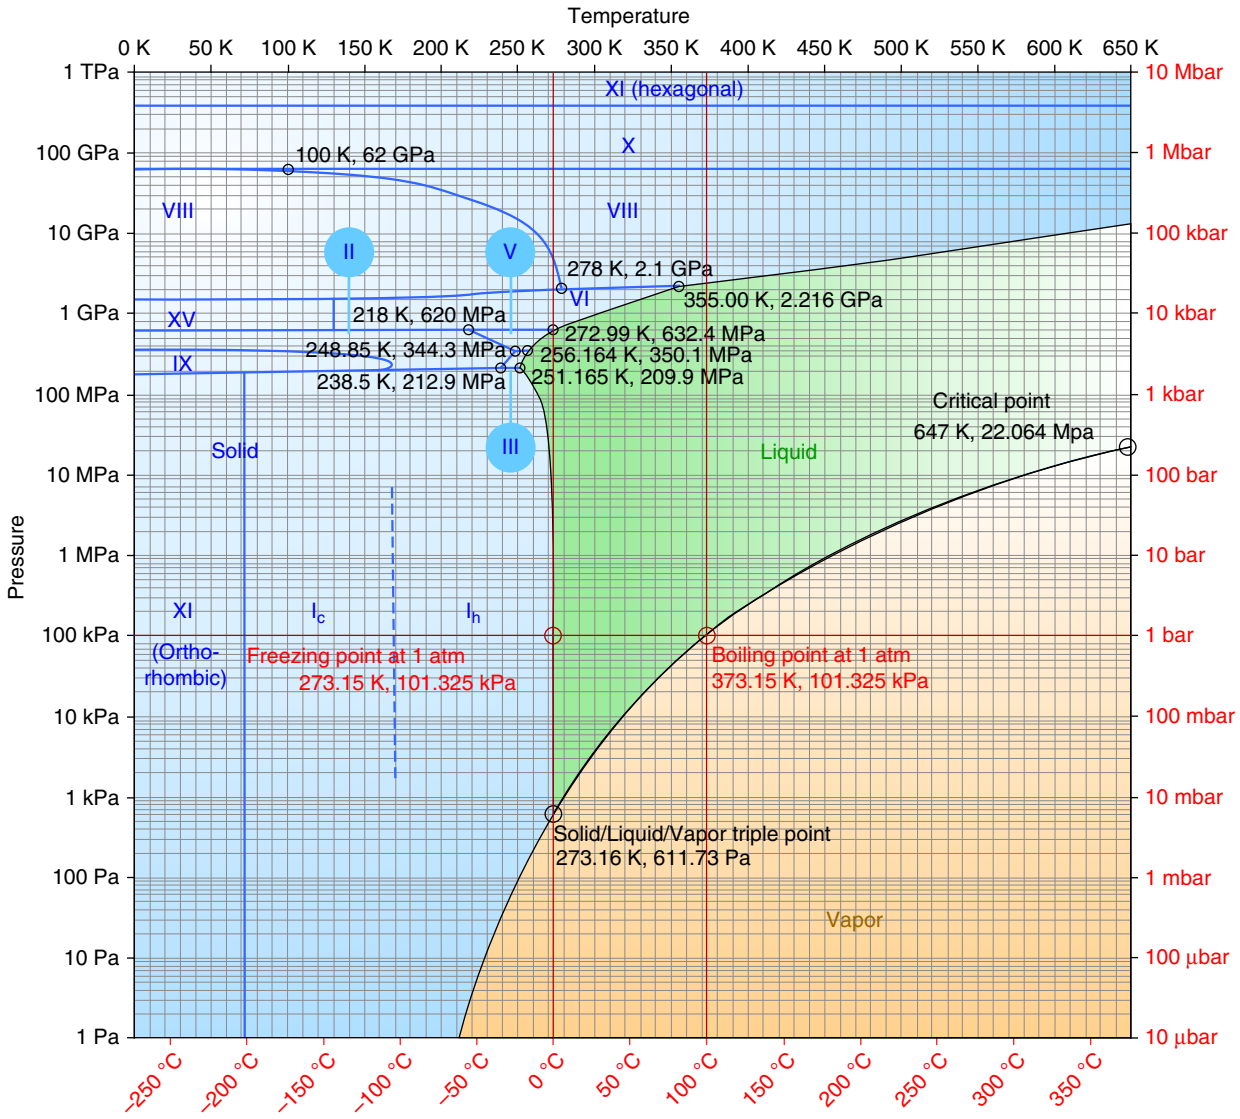

Figure 6 State diagram of water.

Table 5 Allocation of water resources with regard to the distribution of the world population

Continent	*Water availability (%)*	*The world population (%)*
Asia	36	60
South America	26	9
North and Central America	15	5
Africa	11	14
Europe	8	11

Source: Data derived from Figure 5.5 in Saladié, Ò., Oliveras, J., 2010. Sustainable Development. Available at: http://www.desenvolupamentsostenible.org/index.php?option=com_content&id=109&Itemid=174&lang=en (accessed 10.11.13).

Serious problems arise when water supply does not correspond to water consumption, as in India, Northern and Central Asia, and countries around the Mediterranean Sea, the majority of sub-Saharan Africa, the central US, Mexico, and Argentina.

According to various sources, difficulties around the worldwide water supply will increase in the years to come. Estimates predict that in approximately 30–40 years, 3–4 billion people will be affected by severe water shortages. On the demand side, an increase in the world population and an increasing demand by industry have to be accounted for, and in addition there will be an increase in private consumption arising from a strong tendency to urbanization and changes in lifestyle; on the supply side, unlocking the scarce resources will become increasingly difficult because of extreme climate conditions. It is anticipated that the demand for water will increase by 50–64 billion $m^3\,year^{-1}$ in the years to come. One way to cope with the upcoming problems is to minimize the use of water in all water-consuming technologies and production lines, especially in agriculture; as part of this effort, however, the reduction and treatment of wastewater should be considered. According to the presently available technologies,

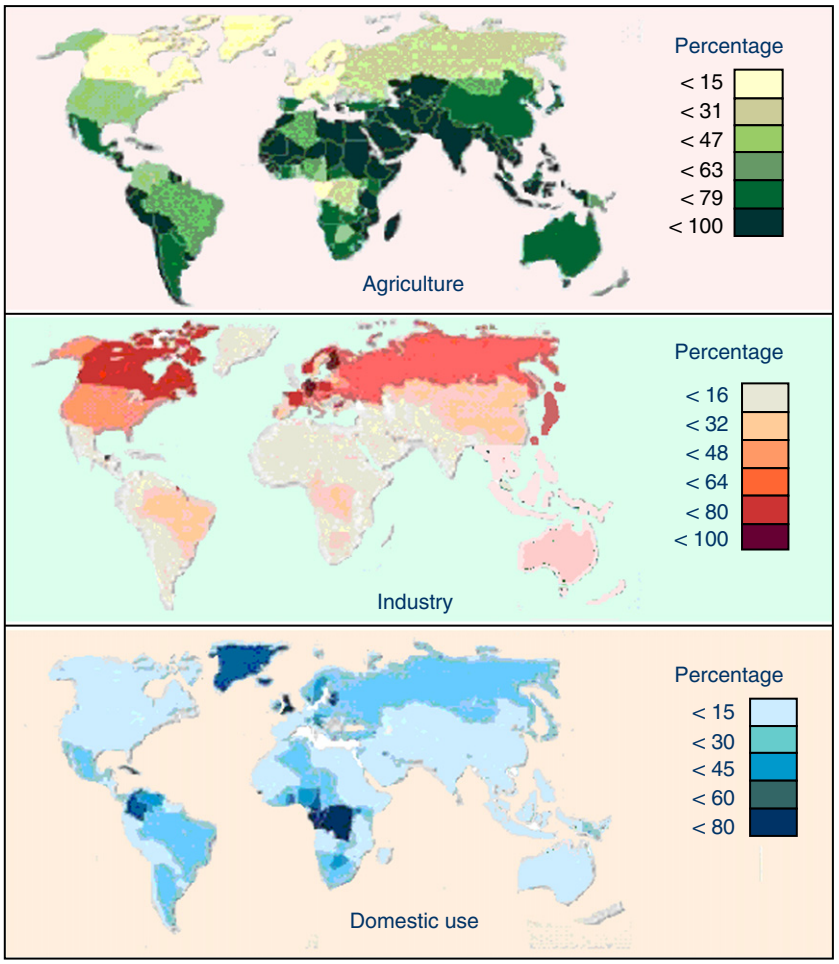

Figure 7 Freshwater withdrawal by sector. Reproduced from Rekacewicz, P., 2000. World Resources 2000–2001. People and Ecosystems: The Fraying Web of Life. World Resources Institute. 1 volume unit of wastewater pollutes 8 volume units of freshwater.

The Virtual Water Concept

Because of the global imbalances in the availability of water which together with other climate factors cause an imbalance in food production, a global trade in food materials of various kinds is required to satisfy the nutritional needs of major parts of the world's population; inherent in this trade is the trade in the water that was needed to produce the agricultural commodities. This water content is called the virtual water content; in other words, the amount of virtual water of a product is the amount of water embedded in that particular product in an imaginary way. Basically, all goods and services that rely in one way or the other on the presence of water 'contain' a virtual amount of water. The term, however, truly makes sense in the case of water that was directly used for the production of a product. Together with complementary information as described below, the indication of the virtual water content of a product or commodity can provide a simple undifferentiated basis for decisions on the production of goods on a local, national, or international level. In a sophisticated model of considering the virtual water content, one has to distinguish between the amount of virtual water which was required to produce a product at its production site and the amount of virtual water which would have been required to produce the product at the site of consumption. This concept can be extended in such a way that not the amount of water to produce a real product is considered, but the amount of water required for a product with a specific nutritional value. This approach would allow defining the virtual water content of sea food, which actually does not require any sweet water for its 'production.' Although there is a large body of data on the virtual water content of agricultural produce in the literature, no reliable data on the virtual water consumption for processing are available.

To allocate and determine the virtual water content of a product is rather difficult, as the virtual water content is influenced by many factors. Hoekstra and his group, who have pioneered the research on virtual water and the WFP

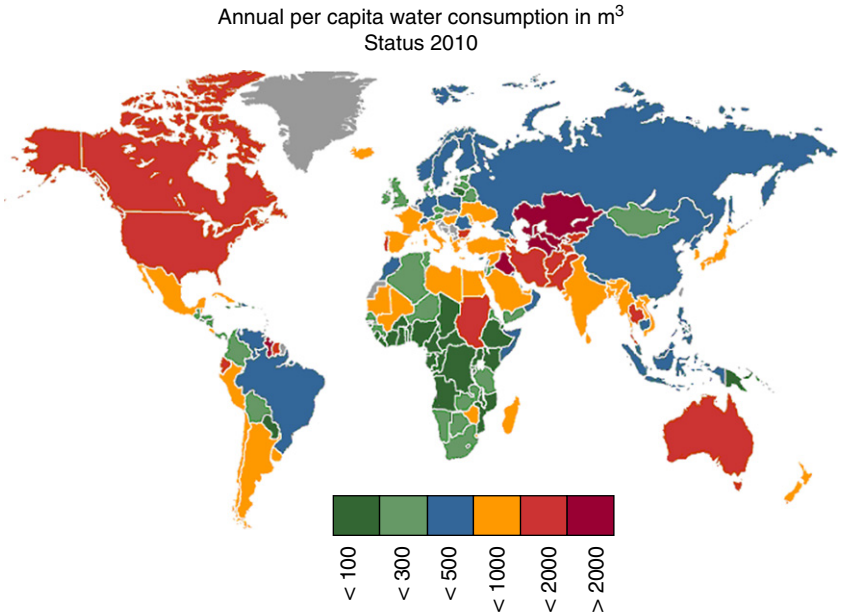

Figure 8 Annual per capita water consumption. AQUASTAT. Available at: http://chartsbin.com/view/1455 (accessed 08.05.14).

(Hoekstra, 2003), recommend that the following factors should at least be considered and preferably provided together with the estimates:

- The place and period (e.g., which year and season) of production. Individual water requirements for plant materials can be calculated for specific countries with the CROPWAT model provided by FAO in conjunction with the CLIMWAT database for climate data and the FAOSTAT database for produce yields. Those data consider also the release of water into the atmosphere through evaporation from the land surface and the transpiration of plants; the sum of the two types of water release is called evapotranspiration (ET). If plants are under water stress, the ET has to be considered through the ET coefficient (Crop evapotranspiration).
- The point of measurement. In the case of irrigated crop production, the question is, for instance, whether one measures water use at the point of water withdrawal or at the field level.
- The production method and associated efficiency of water use. A relevant question is whether water wasted is included in the estimate.
- The method of attributing water inputs into intermediate products to the virtual water content of the final product.
- Denotations of the amount of virtual water should always be presented with a reference base, for example, quantity of water per mass of product (l kg^{-1} or m^3 ton^{-1}) or quantity of water per crop area (m^3 ha^{-1}) or quantity of water consumed per year (m^3 $year^{-1}$) or per person (m^3 cap^{-1}) or even per year and person (m^3 (year × cap)$^{-1}$) etc. If a produce is being processed into various products like wheat

into flour, dunst, cream of wheat, bran, germ oil, etc., the virtual water content of the individual fractions has to be assigned proportionally.

Especially important for optimizing any production of any produce on a global scale is the information on the place of production, its environmental conditions, and the production method. If the water requirements at a specific location, for example, through high ET, are significantly higher than at other locations or than the average, it would appear ecologically and economically worthwhile to consider ceasing this production. Such considerations are especially relevant because the amount of evapotranspired water determines in the first instance the virtual water content of a product, or, as will be demonstrated in this article, the WFP of a product is almost entirely determined through the WFP of the raw material to be processed.

Trading of food commodities means trading the virtual water which is embedded in the produce. According to various studies, the international food-related trade is dominated by the trade in vegetal products, followed by animal products, products of marine origin, and meat. The various published data are not directly congruent but point in the same direction (see also Table 7).

If the international virtual water trade is considered alongside the exchange of food commodities, it becomes obvious that the Americas and Oceania are distinct exporters of virtual water; Asia and Africa, two continents with a huge agricultural production and thus burdened with a high consumption of virtual water, are importers of virtual water; in the case of Europe, which has also a significant agricultural production, exports and imports are almost balanced (see Table 8 and Figure 9).

A further aspect is added to the picture when the production and export/import figures are related to the population of the six continents. The per capita import figures, especially for Africa but also for Asia, indicate that these populations rely heavily on imports; their daily consumption is around 1.1 and 1.4 $m^3\ cap^{-1}\ day^{-1}$, respectively, extremely low compared with the consumption of the average person in the Americas and Europe, at 2.6–3 $m^3\ cap^{-1}\ day^{-1}$. According to Zimmer and Renault (2003), approximately 75% more virtual water would be required if the present world population adopted the diet of the developed countries. The presently low global consumption figures are mainly due to the low virtual water consumption in Asia for details (see Table 9). The tendency in Asian metropolises to move away from a more vegetarian-oriented diet to a more animal product-based diet is therefore an alarming development.

Table 7 Assessment of global virtual water trade between nations (in 2000)

Global virtual water trade (from the perspective of importing countries)	*Volume ($gm^3\ year^{-1}$)*	*Percentage*
Associated with trade of vegetal products	795	60
Associated with trade of animal products	180	13
Associated with trade of meat	173	13
Associated with trade of fish and sea food	192	14
Total	1340	100

The Water Footprint Concept

The idea of considering the use of water along the production, processing, and distribution chain is analogous to the ecological footprint concept of Wackernagel and Rees (1996). For example, the concept of the CO_2 footprint as WFP was developed and widely published by Hoekstra (2003). This concept is based on the virtual water concept of Allan (1994).

Definitions

With regard to its physical localization, two types of 'nonsaline water' are defined for the purpose of the WFP

concept: 'blue water' and 'green water.' Under blue water, groundwater and surface water are understood; this is the fraction of water which is available as drinking water, processing water, and water for irrigation in agriculture; it is used as a transport medium and for many other purposes. Green water is water which is bound in the soil and in green plants; it is, under normal circumstances, the basis for agricultural production. According to Zehnder (2002), approximately 35% of global water resources are available as blue water, whereas the majority of the water resources, i.e., 65%, are available as green water. To account for the amount of water which is being polluted, for example, during processing, a third, notional type of water, 'gray water,' has been introduced (Chapagain and Hoekstra, 2010). Specifically, it is defined as the volume of freshwater that is required to assimilate the load of pollutants based on existing ambient water quality standards (Hoekstra *et al.*, 2009).

Green water provides the basis of agricultural production (see also Section The Virtual Water Concept); the amount used for a specific product is released into the atmosphere through ET. If blue water is being used for plant production, for example, for irrigation it will be also released through ET and it has to be accounted for in a similar way as green water. The scientific methods of determining the share of gray water in a process are still disputed among the experts; it is estimated to be approximately 7% of the total WFP. Gray water is therefore no longer considered in detail in this chapter. Modern agricultural and industrial processes are designed in a way that the amount of gray water is truly minimized.

The WFP of any product can be denoted in various ways, analogous to the denotation of virtual water as water consumed related to the product mass (l kg^{-1} or m^3 ton^{-1}), or related to the crop area (m^3 ha^{-1}), or to the year of production

($m^3\,year^{-1}$), or per person ($m^3\,cap^{-1}$), or even per year and person ($m^3\,(year \times cap)^{-1}$). In normal cases, the presented data refer to the place of origin (cultivation or manufacture).

The WFP is more sophisticated information than the virtual water content. The WFP is an analytical tool to account in a differentiated way for the various issues of direct and indirect utilization and consumption of water for human activities; examples include the production of any type of goods, hygienic measures, services, etc. in and for a country, a municipality, a family, or an individual. In addition, the WFP allows one to indicate whether a certain amount of water has been taken from domestic resources, from a particular catchment area, or from outside a country or continent. In other words, the WFP can be expressed for a nation, a community, a family, an individual, a factory, a processing operation, a service rendered, or anything similar.

Especially in the case of the production of goods, the detailed WFP allows us to evaluate where and when water was withdrawn from its sources and consumed along the supply, production, and processing/distribution chain. The detailed WFP for a product indicates the amount of water which was directly used for individual production and processing steps and, very importantly, for adjunctive measures, as demonstrated by the example of a sugar-containing carbonated beverage 0.5 l polyethylene terephthalate (PET) bottle (Table 17). The WFP cannot be used as an indicator for the impact of water consumption on local environments or as a measure of pollution. If only the green and blue WFP is considered, the WFP allows us to develop water balances for particular activities, areas, individual social groups, communities, or even lifestyles; it therefore allows among other things the comparison and evaluation of specific processing and consumption activities.

The significance of the water footprint

In a global society with an extensive export and import of all types of goods, the WFP allows us, in analogy to the virtual water content, though in a more sophisticated way, to estimate the export and import of two types of water. This is especially of relevance for goods of agricultural origin such as food, cotton textiles, paper, and others, because almost 90% of the world's consumption of water is related to agricultural production.

If the WFPs of larger entities are considered, for example, all food consumed in a specific area or country, one can evaluate which amount and type of water was consumed, where and when the water was withdrawn, and whether the withdrawal was beneficial for the source or not. A comparison of WFPs for various products allows us to determine the ratio of the water consumption for products imported and domestically produced (Hoekstra).

The detailed WFP also allows us in the end to evaluate to what extent the consumption of specific goods or an activity in question is sustainable and socially acceptable or not, if considered with other relevant information such as water availability or sustainability of water utilization. WFP data alone do not offer any clue whether a water source is being overexploited or not; such statements can only be derived from comprehensive water-material balances. This is, for example, of relevance with regard to the question of whether the export/import of commodities with a high WFP such as tropical fruits or any other product from developing countries into developed countries is ethical or not. This question can only be correctly answered when considering all factors around the water resources of the donating country. If the water balance of the producing area is not negatively influenced, no concern should arise (Table 10).

From the data presented in Table 10, it becomes evident that the highly developed countries have a high WFP per capita and year; the US is on top with 2483 $m^3\,cap^{-1}\,year^{-1}$, whereas emerging nations like China, India, and South Africa are much below the global average. India imports only approximately 2% of its WFP compared to Germany, which imports more than 50% of its WFP.

At this point it should be mentioned that the literature provides a treasury of data on all aspects of the WFP as well as on the virtual water content of a great variety of products; not all of these data are congruent, though the tendencies match each other. A rich source of data is provided by Hoekstra and his group, as is evident from the list of references.

Assessing the water footprint

In this article, the WFP for producing and processing of food is being considered; it should, however, be mentioned at this point that the major part of the WFP of any food material derives from the agricultural production; the share of processing is in many cases almost negligible.

In Table 11, data on the total WFP of some products of daily life are presented as a first look at the WFP; of interest are the large differences between, for example, a beef hamburger and a slice of 30 g bread with 10 g of cheese, or a cup of coffee and a cup of tea. The WFP for a large number of produce and products is given in the following tables and in Annex Tables 19 and 20.

The water footprint of processing food

As indicated for almost all activities which consume water, the WFP can be analyzed, estimated, or calculated. As in any analysis, the scope and goal of the analysis and the boundary conditions have to be clear. Reasons for a WFP analysis can be of international, national, or even local interest, or of a private nature. National governments or supranational organizations may have an interest in understanding the flow of virtual water in order to identify stress points, for example, areas of over- or underexploitation, and they might be interested in identifying problem zones and hotspots of water use. Communities of any type may have an interest in understanding whether their particular water resources are managed in a sustainable way; producers/processors of commodities may want to understand whether their use of water is economic, sustainable, and appropriate. Finally, consumers may be interested in learning whether their choice of a product is in compliance with their social attitudes and ethical principles (Hoekstra *et al.*, 2011).

If the WFP of a food product is considered in a detailed analysis, besides production the processing, storage and distribution, retailing, and home preparation and consumption have to be taken into account.

The WFP_p of an individual product, also called its invisible-inherent or virtual weight-related water content, is basically the sum of all WFPs derived from the amount of M (m^3)

Table 10 Composition of the water footprint (WFP) for some selected countries. Period: 1997–2001. Includes both blue and green water use in agriculture

Country	Water footprint		Water footprint by consumption category				
			Domestic internal WFP	Agricultural goods		Industrial goods	
	Total (gm^3 $year^{-1}$)	Per capita WFP (m^3 cap^{-1} $year^{-1}$)	(m^3 cap^{-1} $year^{-1}$)	Internal WFP (m^3 cap^{-1} $year^{-1}$)	External WFP (m^3 cap^{-1} $year^{-1}$)	Internal WFP (m^3 cap^{-1} $year^{-1}$)	External WFP (m^3 cap^{-1} $year^{-1}$)
Australia	26.56	1393	341	736	41	64	211
Canada	62.80	2049	279	986	252	366	166

Source: Reproduced from Hoekstra, A.Y., Chapagain, A.K., 2007. The water footprints of nations: Water use by people as a function of their consumption pattern. Water Resources Management 21, 35–48. doi:10.1007/s11269-006-9039-x.

Table 11 The water footprint of different food products of daily life

Food item	*Unit (kg) (if not otherwise specified)*	*Global average water footprint (l)*
Apple or pear	1	700
Beef 'hamburger'	150 g	2400
Beer (from barley)	1 Glass of 250 ml	75
Bread (from wheat)	1	1300
Bread	1 Slice of 30 g with 10 g of cheese	90
Chocolate	1	24 000
Coffee (roasted)[a]	1 mug of 250 ml	(1450–8375) 5175
Sugar (from sugar cane)	1	1500
Tea	1 mug of 250 ml	30–35
Wine	1glass of 125 ml	120
Cotton T-shirt 8000	200 g	2000
Microchip	2 g	32

[a]Processing is seen to cause the high WFP for roasted coffee beans. For the coffee fruit (coffee cherry) after harvesting the WFP≈2800 l kg^{-1} (global average). As only the seeds (beans) of the coffee cherry can be used while the pulp will be discarded, the utilized mass of product is being reduced. In turn the WFP of this mass will increase accordingly. Drying during the roasting process will further increase the content of virtual water. In contrast, the contribution of the water required during processing to the WFP of the roasted coffee beans remains negligibly small – even in the case of wet processing (approximately 10 l kg^{-1} coffee cherry). Thus, it is not true that processing coffee requires large amounts of water, as is sometimes claimed.

Source: Reproduced from Hoekstra, A.Y., Chapagain, A.K., 2007. The water footprints of nations: Water use by people as a function of their consumption pattern. Water Resources Management 21, 35–48. doi:10.1007/s11269-006-9039 and Hoekstra, A.Y., 2008. The Water Footprint of Food. The Netherlands: Twente Water Centre, University of Twente. Available at: http://doc.utwente.nl/77216/1/Hoekstra08waterfootprintFood.pdf (accessed 11.11.13).

blue water *b*, green water *g*, and gray water *gr* used to process the mass *P* (kg) of a material in *n* process steps *s* which may be operated in parallel or successively:

$$M(b,g,gr)/p = \{\mathrm{WFP}_p = \mathrm{WFP}_{pb1} + \mathrm{WFP}_{pb2} + \mathrm{WFP}_{pb3} \ldots + \mathrm{WFP}_{pbn} + \mathrm{WFP}_{pg1} + \mathrm{WFP}_{pg2} + \mathrm{WFP}_{pg3} + \ldots \mathrm{WFP}_{pgn} + \mathrm{WFP}_{pgr1} + \mathrm{WFP}_{pgr2} + \mathrm{WFP}_{pgr3} \ldots + \mathrm{WFP}_{pgrn}\}[\mathrm{m}^3\ \mathrm{kg}^{-1}] \quad [1a]$$

In other terms:

$$\mathrm{WFP}_p = \sum_{s=1}^{k} (\mathrm{WFP}_{pb} + \mathrm{WFP}_{pg} + \mathrm{WFP}_{pgr})[\mathrm{m}^3\ \mathrm{kg}^{-1}] \quad [1b]$$

where

- WFP_p is the total water footprint for product A expressed in volume water per material mass,
- $\mathrm{WFP}_{pb1}+\mathrm{WFP}_{pb2}+\mathrm{WFP}_{pb3}\ldots+\mathrm{WFP}_{pbn}$ is the sum of blue water footprints,
- $\mathrm{WFP}_{pg1}+\mathrm{WFP}_{pg2}+\mathrm{WFP}_{pg3}+\ldots.\mathrm{WFP}_{pgn}$ is the sum of green water footprints,
- $\mathrm{WFP}_{pgr1}+\mathrm{WFP}_{pgr2}+\mathrm{WFP}_{pgr3}\ldots+\mathrm{WFP}_{pgrn}$ is the sum of gray water footprints,

in *s* process steps and also expressed in volume water per material mass.

In the case of the production of vegetal products the amount of blue and green water is lost through ET.

In process operations during which the mass of the product is submitted to changes (losses and gains), an adequate factor ($PF = P_{inc}/P_{outg}$) has to be introduced into the calculation.

Factors affecting the water footprint of production and processing

Independent of the material to be processed, the first step in evaluating the WFP of a processed product is to establish the flow sheet of the process. For a detailed evaluation, the flow sheet should reflect all relevant steps from raw material production to consumption. Those steps comprise preharvest measures, postharvest processing directly on the field, transport to the processing site or sites, on-site storage or transport to a storage facility, distribution, retailing, and finally home preparation. The flow sheet should also contain an indication of product losses, amounts of water entering and leaving the process, as well as types and amounts of energy used in the process, as well as details on indirect operational features.

In many cases the agricultural produce is preprocessed directly after harvesting; postharvest processing may consist of threshing, dehusking, mechanical dry or wet cleaning, or similar operations.

Final processing, mostly in central processing units, may comprise various types and combinations of classical unit operations, i.e., thermal (blanching, drying, canning, freezing, roasting, etc.) or mechanical processing (sorting, grinding, staining, homogenizing, etc.) operations, packaging, and on-site storage.

The WFP of transportation, storage, and distribution and retailing operations, even when material or commercial goods are transported over long distances or stored over longer periods of time by biofuel energized transportation/storage systems, can be neglected in most cases because it is relatively small compared to the WFP of, for example, agricultural production.

In detail, the WFP has to be calculated on the basis of the water used directly for production (direct operational water) and water which is used to support the production process (indirect operational water) (see also Figure 10).

Water which is used for the agricultural production includes that

- Directly used as green and blue water.
- Indirectly used for fertilizer and other supporting measures, etc.
- Water which is directly used for processing.
- Constitutive water, for example, as part of a beverage.
- Process water, for example, steam generation, washing, cooling, etc., water which is usually discarded after its use and not directly reused; basically it is not to be considered as gray water because it does not necessarily carry any pollutants.
- In addition, there might be a fraction of water which is contaminated by organic materials from various sources (leaching/extraction processes, etc.) and which has to be treated in sewage treatment plants. This fraction of water has to be considered as gray water. In many cases, water received from food processing plants is most welcome by the sewage treatment plants because of its load, which is most favorable for the biological degradation processes in the sewage plants.
- The water which has been used for the adjunctive supply must also be considered in calculating the WFP for direct processing, for example, water used for producing major and even small food additives (spices and condiments), packaging and transport materials, etc.

As water which is indirectly used for processing, all water fractions have to be considered that are used to enable the production as such and for maintaining the processing operations, including the processing environment, administration,

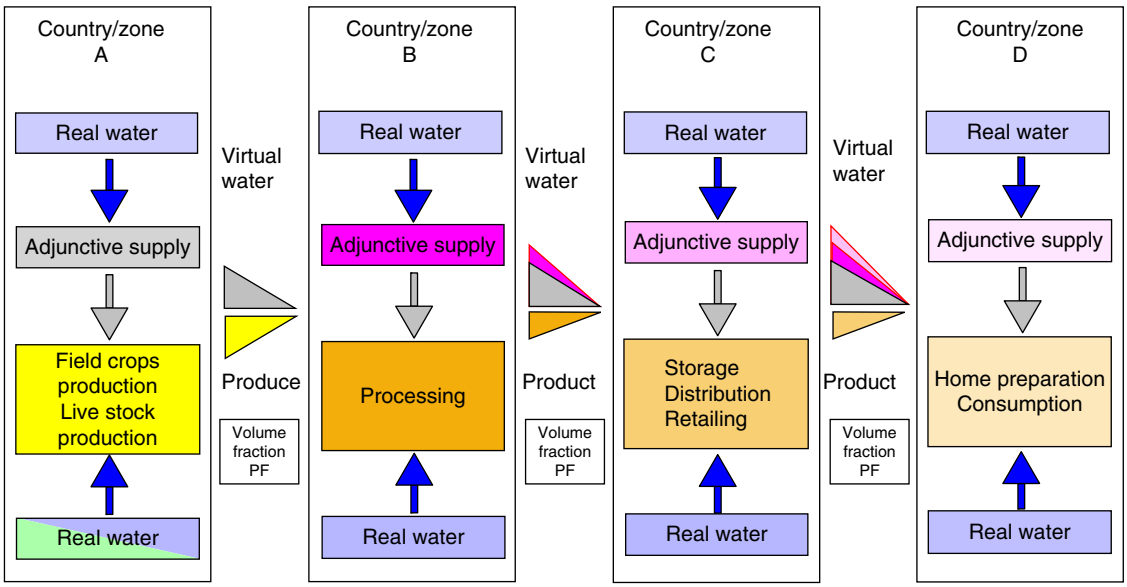

Figure 10 Simplified flow sheet of virtual water. Blue and green stand for blue and green water respectively. Yellow, light brown to very light brown stand for the changes which the raw material undergoes on its way from farm to home preparation/consumption. Grey, dark purple to light purple stand for various adjunctive supplies. PF- Ratio of the volume of the resulting product to the volume of the original product; unit m^3 per m^3.

administrative tools, and different kind of services, etc., for example

- Water used to set up the factory (buildings and machinery).
- Energy in all forms if water is utilized for its production, for example, production of biofuel.
- Water for maintenance and cleaning of processing units, storage facilities, vehicles and vehicle halls, leisure rooms for staff, administrative units inclusive building, etc.
- Water for operating toilets, showers, etc.
- Water for indirect cleaning operations (washing of working garments and personal hygiene of staff).

Water which is used for feeding the staff is usually not included in detailed WFP analysis for a product because those fractions of water are in the general part of different supply chains.

The production of agricultural raw (staple food) materials

The water footprint of meat and animal products

The method of calculating the WFP of an (agricultural) animal product is briefly illustrated by the example of beef (Hoekstra and Chapagain, 2007).

To obtain the WFP of beef, eqn [1] has to be modified in such a way that the various types of actual and virtual water required for raising cattle are reflected in the calculation. Specifically, water is needed for drinking and cleaning purposes (stables, farmyard, animal, etc.), etc., as well as for producing the *feed*.

$$\mathrm{WFP}_{beef} = \mathrm{WFP}_{drink} + \mathrm{WFP}_{feed} + \mathrm{WFP}_{clean}$$

Method of processing: industrial agricultural environment
Output: 200 kg beef
Input:

- 24 m^3 of water for drinking and 7 m^3 of water for cleaning.
- 3060 m^3 of water for producing
  - 1300 kg of grains (wheat, oats, barley, corn, dry peas, soybean meal, and other small grains)
  - 7200 kg of roughages (pasture, dry hay, silage, and other roughage)

Input related in output:

- 155 l water kg^{-1} beef for drinking and cleaning
- 15 300 l water kg^{-1} beef for
  - 36 kg roughage kg^{-1} beef
  - 6.5 kg grain kg^{-1} beef

Total water requirement for producing 1 kg of beef amounts to ~15 500 l, equivalent to 15 500 (m^3 ton^{-1}).

The data presented by Hoekstra and Chapagain have been compiled according to standardized procedures mainly developed by the authors starting around the year 2000; earlier data presented in various sources must therefore be used with precaution, as demonstrated in **Table 12**. The wide span of these data demonstrates the need for standardized data acquisition (Hoekstra *et al.*, 2011).

A detailed compilation of WFP data on major animal products (**Table 13**) indicates that beef has indeed the highest WFP independent of the place of production; the data for beef and pig meat are quite close to each other, with the exception of the data from the Netherlands. Chicken meat is obviously related, with the lowest WFP. The low WFP data for the Netherlands indicate that economic and controlled production methods allow for a low water consumption.

From the data, it becomes evident that the WFP of a specific product may differ considerably across various geographical locations, with, for example, different climates, where an animal/product is raised/grown and where different breeding/cultivation techniques are applied.

The water footprint of vegetal produce

If starch-containing vegetal products are considered, tubers of all kinds have a much lower WFP than cereals; it must, however, be taken into account that cereals have a higher starch content (wheat: ~60% starch) than tubers (potato/cassava: ~16–20%/~35–40% starch). In addition, cereals contain protein (wheat gluten) and oil (maize and wheat). Valuable sources of protein are legumes, which certainly could be used to replace meat (**Table 14**).

All together, the data in **Tables 13** and **14** demonstrate very clearly that "the water footprint of any animal product is larger than the water footprint of crop products with equivalent nutritional value. According to FAOSTAT and other data 29% of the total WFP of the agricultural sector in the world is related to the production of animal products; one-third of the global water footprint of animal production is according to this data related to beef cattle" (Mekonnen and Hoekstra, 2012).

The water footprint of processed products

In most industrialized countries and to some extent also in emerging countries, modern processing technologies are designed in such a way that the use of water is strictly minimized. This is true in cases where water is used for cleaning and washing, steaming, blanching, cooling, and other water-consuming operations. Soiled or otherwise polluted water is mostly cleaned on factory premises and reused; only minor amounts are usually discarded into sewage plants, where they are processed into water of process-water quality.

Including material losses which are process related (e.g., peeling, hulling, boning, and similar operations) into the WFP calculation may increase the WFP for the core product considerably. In the case of major amounts of water used for indirect operations, care has to be taken that these fractions are correctly distributed (taking in account lifespan of utilization and rate of capacity utilization, etc.) to the individual

targeted entities leaving the processing unit or the supply chain if transport, intermediate storage, distribution, and retailing are incorporated in the WFP balance. If several products are manufactured in a processing unit, care has to be taken that individual products are charged with the correct proportion of utilized water. Also, material losses or gains which may occur during processing have to be considered when the WFP for a finished product is being evaluated (**Table 15**).

Considering the example of coffee and tea, it becomes evident that that the WFP increases mainly because of material losses through pulping, hulling, drying and roasting, withering, rolling, and oxidizing/firing, respectively; the technical processes as such do not really contribute to the WFP. The same is true for Coca-Cola and Nestlé's Bitesize Shredded Wheat product. The contribution to the WFP from the process itself is extremely small in the case of Coca-Cola, but packaging adds a significant contribution.

The same picture arises when more complex products like a sugar-containing carbonated beverage and/or Italian pasta and pizza (**Table 16**) are considered; the main contributions to the WFP of such products are caused by the basic raw materials and ingredients. The latter may contribute substantially if they are concentrates or extracts, for example, caffeine and vanilla extract. Processing and indirect operations, for example, construction materials and other materials (indirect operations) such as concrete, steel, paper, natural gas, electricity, vehicles, and fuel, are insignificant with regard to the WFP of the final product.

The WFP of selected materials used directly and indirectly for processing of a 0.5 l PET bottle are detailed in **Table 17**; it becomes obvious that the WFP for PET is rather small, especially when the mass of a 0.5 l bottle is considered. Important in this context is that if several products are manufactured in a factory, the WFP of indirect operations has to be allotted to the

individual products according to their fractions of the total output.

Where the water is used

The conclusion which can be derived from the data presented in Tables 16 and 17 and other data presented reflects the general observation that can be derived from the data presented in Table 20, "Global average WFP of crop products derived from primary crops." The products derived from various primary crops have on average a significantly higher WFP than the original product, almost exclusively because of concentration/extraction processes and not because of the water used in processing operations. It can therefore be stated that the WFP of producing agricultural raw materials

far exceeds the WFP of processing and of all the operations along the food chain, from processing to consumption. Apparent increases in the WFP of a finished product are very often due to the fact that the product was subjected to drying/concentration processes, for example, production of roasted coffee beans or tea leaves. The WFP for various direct and indirect processing operations is in many cases almost negligible compared to the WFP of the raw agricultural product.

The Water Footprint and Water Management

From the data presented it becomes obvious that the WFP of materials, especially food materials, is a powerful tool to control the inherent/virtual utilization of water and the water flow and trade within narrow and broad systems, households, communities, nations, and continents. The various analyses reveal that the major part of water which is used for the global food production and for maintaining the global food supply chain is being used in the agriculture sector. The data also reveal that the WFP of processing steps is minimal compared with the amount of water spend for producing agricultural produce.

One of the merits of the concept is certainly that production methods within countries and between countries with regard to the amount of water used for producing specific goods can be compared. The same is true for the comparison of various production systems and even products; one prominent example in this context is the question whether the proliferation of Western meat consumption habits into Asia, where water and land resources are becoming scarce, should be supported or possibly restricted.

In Table 18 the WFP of a 150 g soy burger is detailed; the total WFP amounts to 157.9 l, the operational WFP amounts to 0.1 l, the WFP of the ingredients to 122.4 l, and the WFP of the other components to 35.4 l; a 150 g beef burger produced in the same country (the Netherlands) has a water consumption of 1000 l. The difference in water consumption between the soy product and the beef product is evident. If the protein contents of the soy product and beef product are considered, it has to be stated, however, that the nutritional-physiological values do not compare one to one. If the protein concentrations in the two products are considered, approximately 290 g of soy protein (tofu) would be required to match 100 g of beef meat (Watzl *et al.*, personal communication). This example demonstrates also that the operational WFP is negligible.

A Major Deficit of the Water Footprint

A major shortcoming of the virtual water and the WFP concepts is that they do not provide any information regarding the sustainability of the water withdrawal from a resource. It is evident that the utilization of 'green' water in agriculture is sustainable; however, if 'blue' water resources are overexploited, i.e., the amount withdrawn is larger than the supply,

an unsustainable situation will arise. To deal with this deficit, Schubert (2011) suggests splitting the amount of blue water into an unsustainable and a sustainable fraction. The problem around this interesting suggestion is that complex and detailed

water balances have to be executed for well-defined control areas.

With regard to food processing and other operations along the food chain, the WFP plays only a minor role. Food science and technology play an important role in reducing the WFP of raw materials through the reduction of food losses starting right after harvest. Reducing post-harvest losses means optimizing the use of available water resources.

Acknowledgment

Major information presented in this compilation has been derived from the large number of detailed publications by Professor dr.ir. A.Y. Hoekstra, A.K. Chapagain, M.M. Mekonnen, A.E. Ercin and M. Martinez Aldaya at the Faculty of Engineering Technology, Department of Water Engineering & Management, University of Twente, P.O. Box 217, 7500 AE Enschede. Arjen Y. Hoekstra and his coworkers have developed the concept of the WFP in an admirable and concise way; they have published a large number of case studies on this subject. Most of the data referenced in this chapter are drawn from the Hoekstra group; those data are easily accessible for further in-depth studies and they have been elaborated under standardized condititions suited for direct comparisons.

Glossary

Adenosine diphosphate (ADP) ribosylation ADP ribosylation is the addition of one or more ADP-ribose moieties to a protein. ADP ribosylation reactions are involved in cell signaling and the control of many cell processes, such as the deoxyribonucleic acid (DNA) repair.

Apoptosis The process of programed cell death, in which the cell uses specialized cellular machinery to catabolize itself in order to control cell number and eliminate cells that threaten survival.

Calvin cycle A series of biochemical light-dependent redox reactions located in the stroma of chloroplasts in photosynthetic organisms.

Cell signaling The process of relaying of molecular signals (chemical or physical, such as light) from a cell's exterior to its intracellular response elements and signaling molecules. The signals may be hormonal (produced in specific cells, glands, or tissues and transported to other parts of the body to provoke a given physiological response), paracrine (cell–cell communication in which a cell produces a signal to induce changes in nearby cells), autocrine (agents arising from the same cells that are signaled), or external in nature (e.g., caused by a given dietary biofactor).

Mitochondriogenesis (mitochondrial biogenesis) The production of new mitochondria; a process that can occur independently of normal cell division.

Myelin An electrically insulating material that forms a protective layer around the axon of a neuron. Loss of myelin leads to a decrease in the rate at which nerve impulses are propagated.

Osteocalcin Proteins secreted by osteoblastic bone cells implicated in bone mineralization and calcium ion homeostasis.

Pentose phosphate pathway Also called the hexose monophosphate shunt pathway; an important source of nicotinamide adenosyl phosphodinucleotide (NADPH) and pentose sugars (5-carbon sugars).

Transcriptional activators and coactivators Transcriptional activators are DNA-binding proteins and function by binding at a DNA site located in or near a promoter of a gene; thus aiding in the enhancement or inhibition of gene expression. Other essential proteins that facilitate the process are called coactivators. They aid in forming complexes that may include the transcription factor and other accessory factors important in the overall regulation of transcription.

Xenobiotic metabolism Metabolic pathways, usually found in the ER, designed to modify the chemical structure of xenobiotics, compounds that are foreign to an organism's normal metabolism, as well endogenously derived products.

Vitamins

The compounds generally classified as vitamins are among those dietary factors for which critical amounts are required for normal physiological processes and functions. As typically defined, vitamins are viewed as essential as they are either not synthesized in endogenous metabolic pathways or in amounts that are adequate for optimal health. Accordingly, dietary sources are required. The dietary amounts needed (usually expressed for humans as an amount per day) in certain cases remain a subject of debate due to differences in opinion regarding the health parameter(s) that are chosen for the establishment of the requirement (Dietary Reference Intakes, 2004).

An appreciation that certain food components can be linked to growth and health has been appreciated for millennia (Carpenter, 1986; Grivetti, 2000; Goldblith and Joslyn, 1964). The Egyptian medical text, the 'Papyrus Ebers' (written approximately CE 1550–70) contains references that described consumption of liver as a potential treatment to improve vision including night blindness. During the Tang Dynasty, the Chinese physician, Sun Simiao, wrote medical texts that contained nutrition guides that are still used in traditional Chinese medicine. By the sixteenth century, fresh fruits and vegetables were documented as effective in the treatment of scurvy and by the late 1800s, an association between the consumption of certain foods and prevention from other disease conditions could be inferred; as examples, the association between maize and pellagra (Section Niacin) and between polished rice and polyneuritis (Section Thiamine) can be considered.

At this point, seminal concepts were also emerging that accelerated progress in identifying specific compounds in foods as nutritionally essential. Analytical approaches were developed that focused on defining the composition of foods. The utility of using experimental animals as models for nutrition and toxicological studies was appreciated, along with food-derived energy concepts, that is, the association between caloric intake and work (e.g., by the early twentieth century, the physiological

 doi:10.1016/B978-0-444-52512-3.00071-1

fuel values for fat, carbohydrate, and protein were established). There was also a good understanding that indices, such as the respiratory quotient, could change depending on the composition or the amount of a food that was consumed. However, at this time, the concept of disease was largely based on the 'germ theory of disease' proposed by Pasteur and others, that is, diseases were caused by infectious agents (Toledo-Pereyra, 2009). It was also commonly held that only the gross constituents of the diet, that is, carbohydrates, protein, fat, and minerals, were needed for complete nourishment.

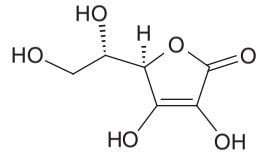
As an example, an early explanation related to the ability of a factor isolated from rice husks to reverse the signs of beriberi (a disease associated with thiamine deficiency) was that beriberi was caused by an infectious agent or toxin in rice polishing and the husks of rice contained some type of antidote. Nevertheless, the more nutritional explanation eventually prevailed, that is, that rice contains an essential factor in the outer layers of the grain that on its removal (e.g., by polishing) potentiated a type of nutritional 'deficiency disease.' When coupled with the observations of E.V. McCollum and M. Davis and those of T. Osborne and L. Mendel, that a factor in butter and egg yolk was necessary for growth and vision in rats, a true step forward was achieved. The fat-soluble component in butter and egg yolk was designated factor A. The factor in rice hulls was designated factor B (later B_1, on discovery of other essential factors). As the concept of essential factors was further solidified, the term *vitamine* was coined and used as early as 1912 (by the Polish biochemist, Kazimierz Funk). The term was a combination of 'vital' and 'amine,' meaning amine of life. As the list of factors grew and better chemical characterizations became possible, it became evident that not all vitamins could be classified as amines. Thus, *vitamine* was shortened to vitamin (Goldblith and Joslyn, 1964).

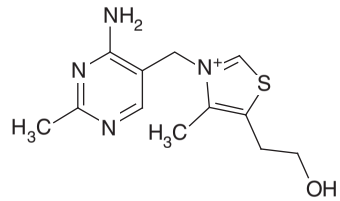
As of 2013, there are 13 compounds and related vitamers (i.e., physiologically active isomers and precursors) that are widely accepted by the scientific community as meeting the criteria for being classified as vitamins for humans. Specific subcategories and further classifications are arbitrary and based on general biological activity, chemical properties, and historical precedents (**Table 1**). For example, the letter designations for vitamins (e.g., vitamins A, B_1, B_2, or C, etc.) evolved in part from their sequential discovery. Not included in this discussion are a number of compounds that are often described as conditional/vitamin-like compounds. Many of these compounds are derived from amino acids. Included in this group of compounds are carnitine, various carotenoids, choline, glutathione, inositol, lipoic acid, and taurine. Selected phytochemicals (historically designated as vitamin P) and polyquinones, such as pyrroloquinoline quinone, are also sometimes included.

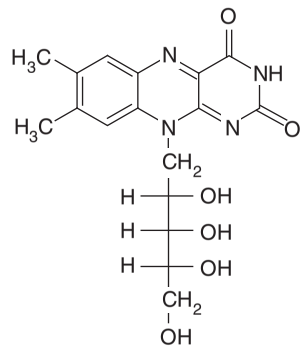
Health Effects: General Properties and Primary Functions of Vitamins

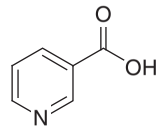
The need for vitamins stems in part from our evolution from prokaryotes and eukaryotes wherein energy utilization involved the need for oxidation of inorganic compounds, nitrogen fixation, and phototrophic processes (e.g., the presence of a Calvin cycle). Although animals no longer have the ability to capture solar energy or fix nitrogen, remnants of such processes have been retained as essential features of energy-related metabolism (e.g., the ability to effect energy and proton gradients, maintain energy charge, or catalyze the formation of high-energy intermediates). Further, whether aerobic or anaerobic, the need to deal with reactive oxygen species (e.g., superoxide and hydrogen peroxide) has resulted in the need for compounds, such as the tocopherols (e.g., compounds with antioxidant potential, such as vitamin E). To transfer heat and engage in work efficiently, living systems maintain their state of complexity by increases in entropy. In this regard, to circumvent prohibitive energy barriers and increase the ability to incrementally regulate energy processes, ranges of catalysis with differing attributes are needed. Vitamin-derived cofactors, along with given mineral elements, provide such range and diversity. Specific vitamins have largely evolved to extend the catalytic capacity of enzymes (e.g., beyond that is provided by amino acids) and provide novel catalytic or cell regulatory and signaling functions. Examples include functioning as agents for electron transfer, carbonium and carbanion stabilization, nucleophilic and electrophilic transfers, carbonyl-amine reactions, and oxidative and nonoxidative bond cleavage. With such cofactors, the metabolism of a cell is more easily achieved, particularly the coupling of the spontaneous processes of catabolism to the nonspontaneous processes of anabolism (McCormick, 2007).

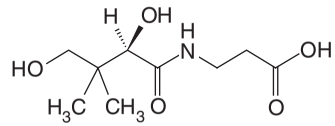
Most vitamins act as a coenzyme, cosubstrate, or as a prosthetic group. A coenzyme is defined as an organic molecule that binds specifically within an apoenzyme to create a catalytically competent holoenzyme. If tightly bound and nondissociable, a coenzyme may be referred to as a prosthetic group, and if readily dissociable, they may be called cosubstrates.

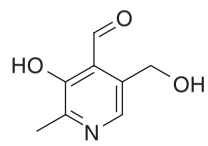




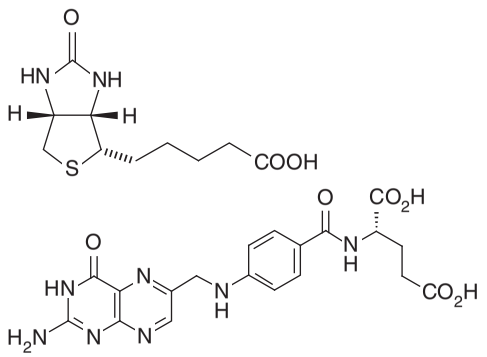


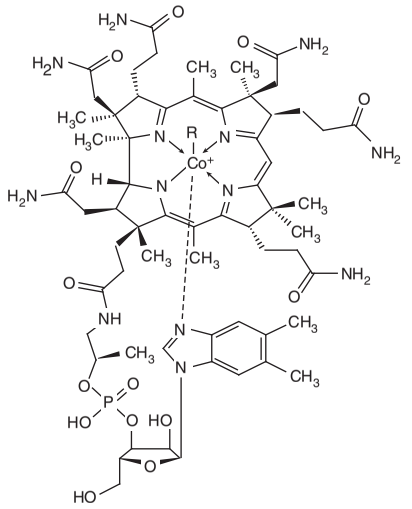


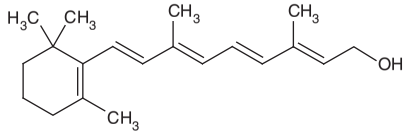




Important Systemic Functions of Vitamins



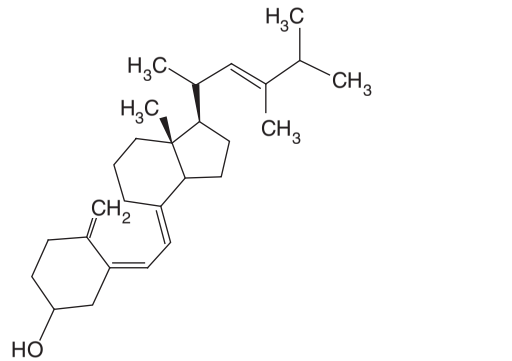


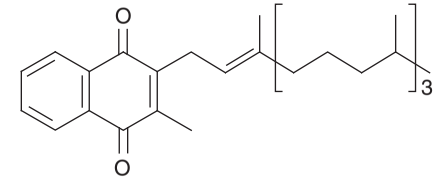


Vitamins involved in oxidation–reduction reactions

- Ascorbic acid

  Ascorbic acid (vitamin C; 2,3-enedial-gluconic acid) is a powerful reducing agent. Both hydrogens of the enediol group in ascorbic acid are capable of dissociation. Reductions initiated by ascorbic acid usually occur in a stepwise fashion with monodehydroascorbic acid, as a semiquinone intermediate. This intermediate then disproportionates to dehydroascorbic acid. Ascorbic acid serves as a cofactor for mixed-function oxidations catalyzed by microsomal mono-and dioxygenases, which are commonly referred as hydroxylases and oxidases. These enzymes catalyze the hydroxylation of prolyl and lysyl residues in collagen and proteins with collagen-like domains as well as elastin, conotoxins, argonaute 2, and C1q-complement (Rucker *et al.*, 2008). The hydroxylation of carnitine, neurotransmitters, the synthesis and catabolism of tyrosine, and the metabolism of numerous xenobiotics and secondary metabolites by microsomal oxidases are also dependent on ascorbic acid.





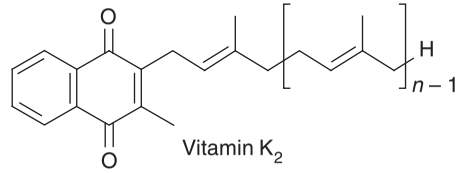


Table 1 Vitamin sources and requirements

Vitamin	*Human adult requirements females–males amount per day*	*Common sources*	*Chemical structure*
Water-soluble vitamins			
Ascorbic acid (vitamin C)	45 mg (RDA)[a] 60 (DRI)[c]	Red and green peppers, various citrus fruits, and broccoli	
Thiamine (vitamin B_1)	1.0–1.5 mg (RDA)[a]	Whole grains, lentils and beans, and fish (e.g., tuna)	
Riboflavin (vitamin B_2)	1.1–1.8 mg (RDA)[a]	Eggs, milk, and legumes	
Niacin and nicotinic acid (vitamin B_3)	14–20 mg (RDA)[a]	Meat, fish, poultry, whole grains, and high-quality protein sources containing ample tryptophan	
Pantothenic acid (vitamin B_5)	~5 mg (AI)[b]	Chicken, beef, potatoes, oats, cereals, and tomatoes	
Pyridoxine (vitamin B_6)	1.5–2.0 mg (RDA)[a]	Grains, cereals, soy products, and organ meats	
Biotin (vitamin H or B_7)	~30 μg (AI)[b]	Liver, fruits, and meats	

Folic acid, folacin (vitamin M or B_9)	400 μg (RDA)[a] 200 μg (DRI)[c]	Dark, leafy vegetables; whole grains; and fortified breads and cereals	
Cobalamin (vitamin B_{12})	3.0 (RDA)[a] 2.0 (DRI)[c]	Fish, poultry, meat, and fortified cereals	
Fat-soluble vitamins			
Vitamin A (retinol)	800–100 μg (RDA)[a]	Sweet potatoes and related tubers, carrots, and Brassica family leafy vegetables (e.g., spinach and kale)	
Vitamin D (calciferol)	400 μg (RDA)[a]	Fish liver oils, fortified milk products and cereals, and also sunlight exposure	

(*Continued*)

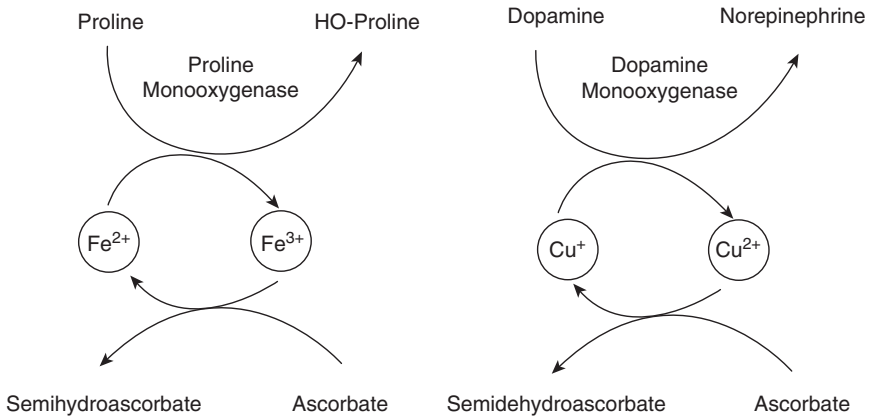

Table 1 Continued

Vitamin	*Human adult requirements females–males amount per day*	*Common sources*	*Chemical structure*
Vitamin E (tocopherol)	12–15 mg (RDA)[a]	Plant and plant germ seed oils, plant seeds, and nuts	
Vitamin K_1 and K_2	55–80 μg (RDA)[a]	Green vegetables	 Vitamin K_1  Vitamin K_2

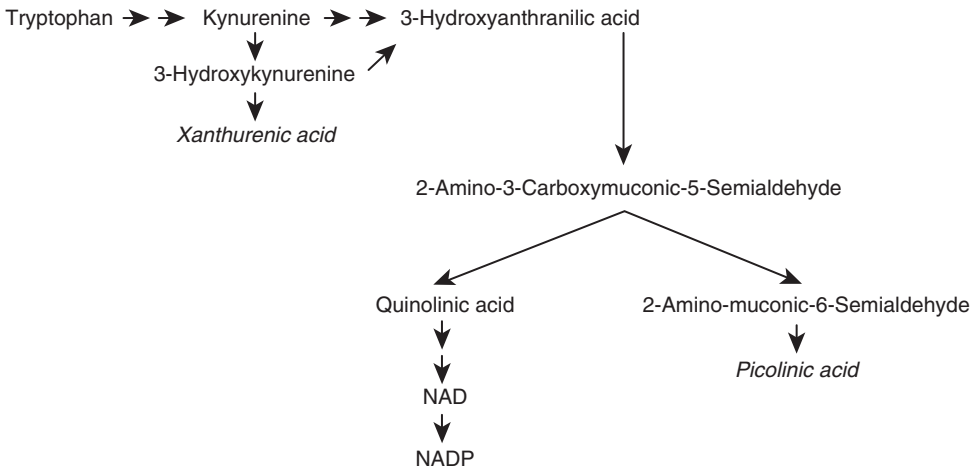
[a]The range of values reflects those for young females and males. Values are recommended dietary allowances (RDAs), defined as the quantities of nutrients in the diet that are required to maintain good health in people. RDAs were established by the Food and Nutrition Board of the National Academy of Sciences, and are periodically revised.

[b]When there are insufficient data to estimate a RDA or dietary reference intake (DRI), an adequate intake (AI) estimate is used, which is a based on intake levels derived from food compositional data, rather than nutritional balance data that requires knowledge of relative absorption and whole body retention.

[c]The DRI was introduced in 1997 in order to broaden the existing guidelines known as RDAs. The DRI values, however, are not currently used in nutrition labeling.

The hydroxylases and oxidases that require ascorbic acid often have iron and copper at their catalytic sites. In this regard, ascorbate acts as a reducing agent, donating electrons and preventing oxidation, which maintains iron and copper atoms in a reduced state (Mandl *et al.*, 2009). This is needed for the coordination of oxygen leading to favorable transfer to various substrates. Peptidylglycine α-amidating monooxygenase also requires ascorbic acid. The protein contains two enzymes that act sequentially to catalyze the α-amidation of neuroendocrine peptides important to their activation.

$$\text{Peptidylglycine} + \text{ascorbate} + O_2 \rightarrow$$
$$\text{peptidyl-(2-hydroxyglycine)} + \text{dehydroascorbate} + H_2O$$



The first step of the reaction is catalyzed by peptidylglycine α-hydroxylating monooxygenase; peptidyl-α-hydroxyglycine-α-amidating lyase catalyzes the second step of the reaction.

When the activity of ascorbic acid-dependent hydroxylases or oxidases is limited, the result can be a decreased production of proteins, such as collagen (the major structural protein in the body) or select components of the immune system (e.g., such as the C1q complex, important for immunoglobulin binding and interactions). Further, important metabolites, such as carnitine (important for fatty acid transport into the mitochondria) can be affected. Accordingly, the result of ascorbic acid deficiency or 'scurvy' can be capillary fragility, delayed wound healing, impaired immune responsiveness, and impaired bone formation. Described in the classic treatise by Lind, scurvy was one of the most common diseases associated with maritime travel, often killing large numbers of the passengers and crew on long-distance voyages or migrations of people without ready access to fruit and vegetable sources of ascorbic acid.

- Niacin

  Niacin is an unsubstituted pyridine-3-carboxamide. With respect to redox functions, nicotinamide adenosyl dinucleotide (NAD) and nicotinamide adenosyl phosphodinucleotide (NADP) are the coenzymes derived from niacin that are designed to facilitate the abstraction of a hydride ion (H:) from substrates. These cofactors are produced in reactions that link potential niacin precursors to adenosyl phosphates (McCormick, 2007).

  In many animals, NAD and NADP can be formed from metabolites arising from tryptophan catabolism as outlined in the following schema. NAD (containing niacin) is eventually formed following amidation; a subsequent phosphorylation leads to NADP. Xanthurenic and picolinic acid are principal excretory products. Factors that stimulate their production compromise NAD production. Virtually all cells are capable of converting niacin into NAD or NADP.

NAD and NADP function in numerous oxidoreductase systems (e.g., dehydrogenase or reductase systems) important to the conversion of alcohols (sugars and polyols) into aldehydes or ketones, hemiacetals into lactones, aldehydes into acids, and certain amino acids into keto acids. From a redox perspective, NAD is often utilized in catabolic pathways and NADP in synthetic pathways. In addition, NAD serves as a substrate in mono- and poly-adenosine diphosphate (ADP)-ribosylation reactions. ADP ribosylation occurs with the addition of one or more ADP-ribose moieties to a protein. ADP ribosylations are important in cell signaling and the control of many cell processes, including deoxyribonucleic acid (DNA) repair and apoptosis. In many cells, more than 50% of the cell's NAD may be directed or involved in some type of ribosylation reaction (Kirkland, 2013).

A severe deficiency of niacin can result in pellagra (characterized by diarrhea, dermatitis, forms of dementia, and eventually death). Pellagra may be first present with sensitivity to sunlight; followed by dermatitis, alopecia (hair loss), edema (swelling); glossitis (tongue inflammation); mental confusion; and ataxia (lack of coordination). Other mental disturbances can include restlessness, tense and quarrelsome behavior, and paranoid emotional disturbances.

Pellagra was once endemic in the southern parts of the United States, the disease being particularly common in individuals housed in jails, as well as children in orphanages. With the recognition of the dietary causes of pellagra in the early 1900s, the disease was largely eliminated in the United States by the 1940s (Goldblith and Joslyn, 1964); however, pellagra remains endemic in parts of Africa, where corn is a major dietary staple. A deficiency of niacin can result from either a dietary insufficiency of niacin per se or the predominant consumption of protein sources, such as maize. The nutritional availability of niacin from maize is poor and the concentration of the amino acid, tryptophan is also low. For example, sufficient quantities of niacin may be obtained from high-quality proteins, rich in tryptophan (Kirkland, 2013).

- Riboflavin

  Riboflavin (7,8-dimethyl-10-[(*2S,3S,4R*)-2,3,4,5 tetrahydroxypentyl]benzo[*g*]pteridine-2,4-dione) is present in tissue and cells as flavin adenine dinucleotide (FAD) and flavin adenine mononucleotide (FMN). FAD and FMN are cofactors in aerobic processes, usually for oxidases, although FAD can also function in anaerobic environments as a dehydrogenase cofactor.

  In some enzymes, riboflavin is covalently linked (e.g., succinic dehydrogenase in which riboflavin is linked to a specific histidinyl residue). In general, FMN and FAD, even when not covalently bound, are not easily dissociated; thus, they may often be viewed as prosthetic groups. Flavins catalyze one-electron and one-proton transfer reactions. Oxygen is utilized as a cosubstrate. Flavins also act as oxidizing agents, because of their ability to accept a pair of hydrogen atoms. Substrates for flavin-requiring enzymes are usually compounds that contain carbon–carbon double bonds and disulfide-containing compounds (e.g., oxidized lipoic acid). Reduced NADP commonly serves as a reductant in processes to regenerate $FADH_2$ or $FMNH_2$ (McCormick, 2007).

Signs of riboflavin deficiency include lesions of the oral cavity, the lips, and the angle of the mouth (cheilosis), inflammation of the tongue (glossitis), and a seborrheic dermatitis that presents as scaly, flaking, and inflamed skin. The sebaceous-gland-rich areas of the skin (e.g., the nasolabial fold) and scalp are most affected. The filiform papillae of the tongue may also be lost with changes in color from pink to magenta. Anemia and increased vascularization of the eye are present in some animals with riboflavin deficiency (Rucker *et al.*, 2008).

Vitamins important to the generation of leaving group potential

- Thiamine

  Thiamine (2-[3-[(4-amino-2-methyl-pyrimidin-5-yl) methyl]-4-methyl-thiazol-5-yl] ethanol) is central to the metabolism of carbohydrates as energy sources. The five-member (thiazole) ring of thiamine is an arrangement of atoms (–N═CH–S–) called an ylide. The central carbon has carbanion character that acts as an electron-rich center for reactions at which a carbonium ion is the potential point of attack, such as the α carbon of ketoacids, common intermediates in the oxidation of carbohydrates. In addition, the ylide configuration provides a transitory matrix that has a good leaving group and transfer potential.

  Thiamine pyrophosphate (TPP) is the major coenzyme derived from thiamine, for which there are two general types of reactions. The first is the decarboxylation of α-keto acids (the condensation of the thiazole moiety of TPP with the α-carbonyl carbon on the acid leads to loss of CO_2 and production of a resonance-stabilized carbanion). An example is the first step in the tricarboxylic acid cycle (TCA) cycle involving oxidation of pyruvate (**Figure 1**). The second type is the transketolase reaction that reacts with a carbonyl group, cleaves the adjacent carbon–carbon bond, and then transfers the cleaved moiety to another aldose substrate subunit. The pentose phosphate pathway is especially active in the adipose tissue, mammary glands, and the adrenal cortex, but it is more limited in the skeletal muscle and liver.

  The two stages of the reaction are reversible. This pathway can bring about the interconversion of pentoses, hexoses, and other lengths of sugars as needed. The pentose phosphate pathway also generates the reduced form of NADP, which in turn is required for a wide range of biosynthetic reactions, including the synthesis of fatty acids. The fundamental reaction is a two-carbon (glycolaldehyde group) transfer from one sugar phosphate to another.

  Xylulose-5-phosphate (C5) + Ribose-5-phosphate (C5)

  ⇆Glyceraldehyde-3-phosphate (C3)

  +Sedoheptulose-7-phosphate (C7)

  Xylulose-5-phosphate (C5) + Erythrose-4-phosphate (C4)

  ⇆Glyceraldehyde-3-phosphate (C3)

  +Fructose-6-phosphate (C6)

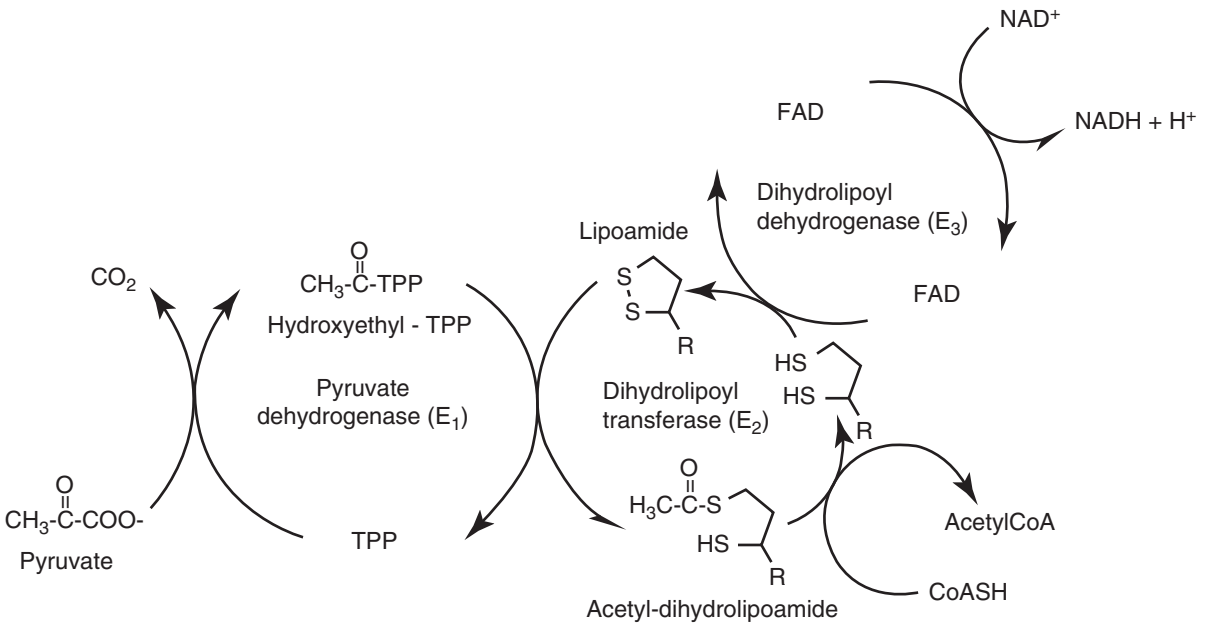


Figure 1 Thiamine. Thiamine in the form of thiamine diphosphate (TDP) is an essential cofactor for the pyruvate dehydrogenase (PDH) complex, which is composed of three enzymes that catalyze the conversion of pyruvate into acetyl-CoA. Acetyl-CoA may then be used in the citric acid cycle to carry out cellular respiration. This complex is also related structurally and functionally to the oxoglutarate dehydrogenase complex (found within the citric acid cycle), as well as the oxoacid dehydrogenase multienzyme complexes important to the metabolism of branched-chained amino acids. Given its central role in carbohydrate and energy metabolism, PDH is regulated in part by changes that affect ATP production or the production of cellular oxidants or reductants important to energy utilization (e.g., NAD and NADP derivatives).

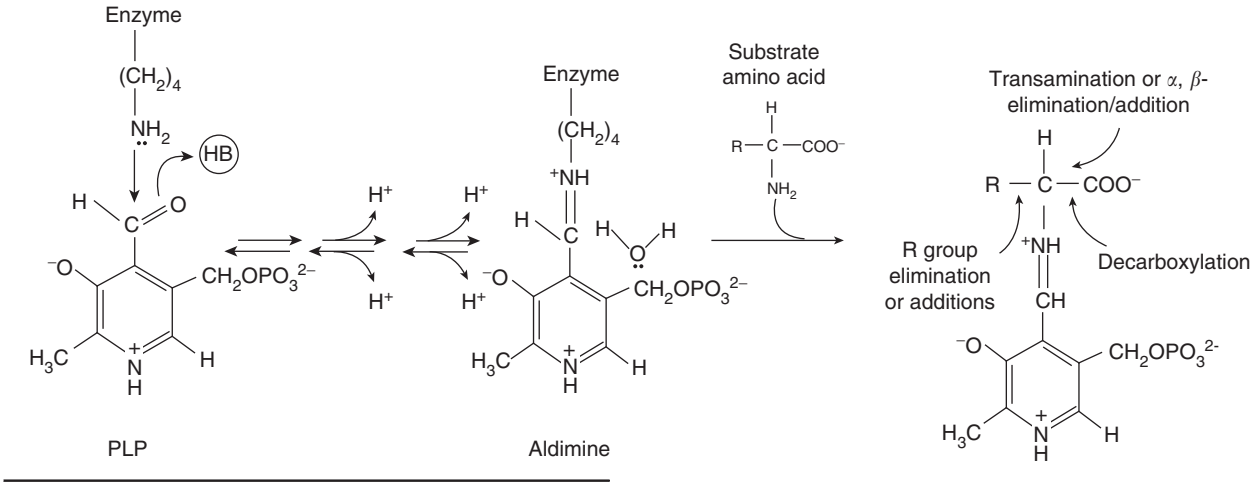
Transketolase acts in conjunction with the enzyme transaldolase (nonthiamine-requiring), which catalyzes

Sedoheptulose-7-phosphate (C7)
+ Glyceraldehyde-3-phosphate (C3)
⇆Erythrose-4-phosphate (C4)
+Fructose-6-phosphate (C6)

Other forms of thiamine include adenosine thiamine triphosphate (TPPP) or thiaminylated adenosine, which accumulates in bacteria as a result of carbon starvation. It is also present in low amounts in yeast, roots of higher plants, and animal tissue. In neural tissue, TPPP is a neuroactive form of thiamine thought to be involved in sodium and potassium gating (transport) in neural cells. TPPP also exists in bacteria, fungi, and plants. Like thiaminylated adenosine, it seems to play a role in response to carbon or amino acid starvation.

In the TCA cycle, the principal enzymes affected by thiamine deficiency are PDH and α-ketoglutarate dehydrogenase. Accordingly, thiamine deficiency adversely affects any organ system dependent on oxidative metabolism. Thiamine deficiency commonly presents subacutely, but can eventually lead to metabolic coma and death. A lack of thiamine can be caused by malnutrition, diets high in thiaminase-rich foods (raw freshwater fish, raw shellfish, and ferns), foods high in antithiamine factors (e.g., tannins and caffeic acid found in tea and coffee), and gastrointestinal diseases induced by alcohol or systemic inflammation.



Syndromes caused by thiamine deficiency include beriberi, which causes cardiomyopathy and weakness due to impaired pyruvate and eventual Adenosine triphosphate (ATP) production and Wernicke–Korsakoff syndrome which expresses as a triad of symptoms: ocular disturbances, changes in mental state, unsteady stance, and gait. Although the mechanisms underlying the neurologic responses to thiamine deficiency have been firmly established, low levels of TPPP are thought to play a role. TPPP is the major form of thiamine in neural tissue. There is evidence that suggests that TPPP may be important in maintaining normal voltage-gated ion channels in nerve tissues. Voltage-gated ion channels are a class of transmembrane ion channels that are activated by changes in electrical voltage potential and are especially critical in neurons (Oliveira *et al.*, 2007).

- Pyridoxine

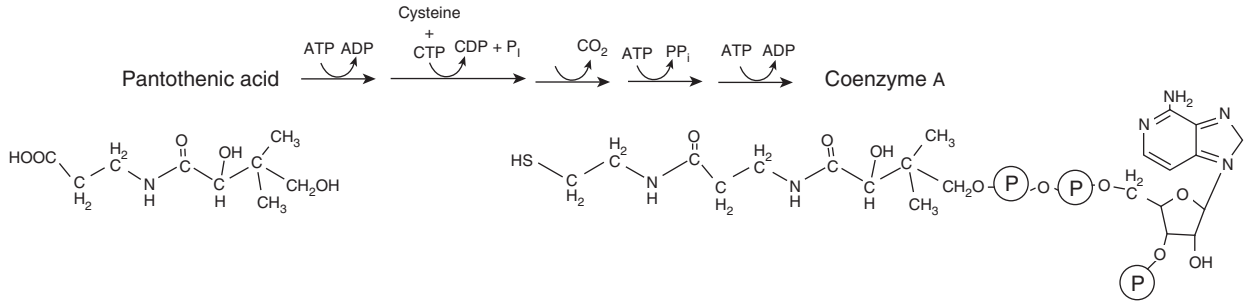
  Pyridoxine or vitamin B_6 is a collective term for pyridoxine, pyridoxal, and pyridoxyl amine. Pyridoxine is most abundant in plants; pyridoxal and pyridoxyl amine are most abundant in animal tissues. Although vitamin B_6 deficiency is rarely seen as most diets provide adequate amounts of the vitamin, drug-induced vitamin B_6 deficiency can occur following administration of certain drugs, such as isoniazid or penicillamine or naturally occurring antagonists. Isoniazid (used to treat tuberculosis) is a hydrazide that can form hydrazone derivatives with pyridoxal moieties, which in turn act as inhibitors of B_6-requiring enzymes. Penicillamine (β-dimethylcysteine) used in the treatment of Wilson's disease also can interfere

with normal B_6 metabolism due to the formation of thiazole derivatives. A naturally occurring antagonist to vitamin B_6, linatine (1-amino-D-proline), which is present in flaxseed can also be a stable product with pyridoxal phosphate.

Accordingly, a consequence of a severe B_6 deficiency can be a microcytic anemia due to impaired heme production.

The complications from B_6 deficiency are to a large degree a consequence of insufficient activity of pyridoxal-5′-phosphate (PLP)-dependent enzymes. The major form of vitamin B_6 in cells is PLP; vitamin B_6 is essential for amino acid synthesis and catabolism. The ability of PLP to condense its 4-formyl substituent with an amine, usually the α-amino group of an amino acid, to form an azomethine (Schiff base) linkage, produces a conjugated double-bond system extending from a carbon of the amine (amino acid) to the pyridinium nitrogen in PLP. This results in reduced electron density around the α-carbon, which in turn weakens each of the bonds to facilitate the transfer reactions. There are three major types of pyridoxine-dependent reactions: decarboxylation reactions, transaminations, and elimination/addition reactions. Decarboxylations include the conversions of tyrosine to tyramine, 5-hydroxytryptophan to serotonin, histidine to histamine, and glutamate to γ-aminobutyric acid (GABA). Signs of convulsions associated with severe vitamin B_6 deficiency are often associated with impaired GABA metabolism. Transaminations are reversible oxidation–reduction reactions in which an amino group is transferred typically from an α-amino acid to the carbonyl carbon atom of an α-keto acid. The inability to effectively utilize protein as an energy source or use the given amino acids as gluconeogenic precursors result from compromised transaminase activity. Elimination and addition reactions include electron withdrawal from the β-, γ-carbons of amino acids. This sets the stage for hydride condensations or aldol reactions (McCormick, 2007). Examples of aldol and hydride reactions are the conversion of serine to glycine and the formation of α-aminolevulinic acid, the first step in heme biosynthesis.

Another novel reaction, not directly linked to amino acid metabolism, is the role of vitamin B_6 as a cofactor for glycogen phosphorylase. The phosphate group on PLP donates a proton to an inorganic phosphate molecule, allowing the inorganic phosphate to, in turn, be deprotonated by the oxygen forming the α-1,4 glycosidic linkage (Fischer, 2013). The overall reaction is



$$(\alpha\text{-1,4 glycogen chain})_n + \text{Pi} \leftrightarrows (\alpha\text{-1,4 glycogen chain})_{n-1} + D\text{-glucose-1-phosphate}$$

Although the reaction is reversible in solution, within the cell the enzyme only works in the forward direction as shown above because the concentration of inorganic phosphate is much higher than that of glucose-1-phosphate.

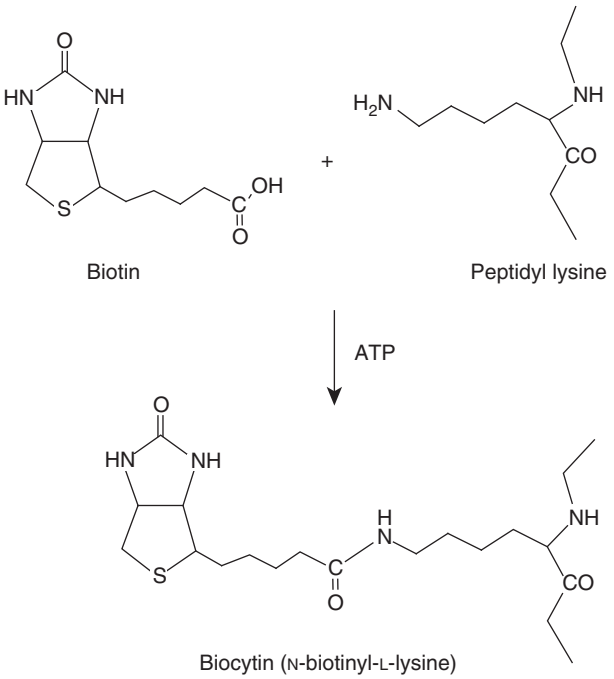
Acyl activation and transfer

- Pantothenic Acid

  Pantothenic acid is a precursor of coenzyme A and the prosthetic group of the so-called acyl carrier protein domain in certain enzymes (e.g., fatty acid synthase). The active form of the cofactor is produced by the formation of a peptide bond to cysteine followed by decarboxylation of the cysteine residue, and then by conjugation to the remainder of the coenzyme. The thiol ester at the terminus of coenzyme A enhances the activation of acyl compounds for ultimate attack of their carbonyl functions by nucleophiles. The carbonyl carbon of a thiol ester (CoA–S–C═O–R) is more positively polarized and less stabilized by resonance than a corresponding oxy ester (CoA–O–C═O–R). Thus, the acyl moiety is relatively activated for transfer and is often described as a high-energy bond.

Modifications of acyl side- or tail-chains may also be enhanced. Thioesters more easily undergo enolization by permitting the removal of hydrogen as a proton than oxyesters. The enolate that is formed is stabilized by delocalization of its negative charge between a carbon and the acyl oxygen, which makes it thermodynamically more accessible as an intermediate. As the developing charge is also stabilized in the transition state that precedes the enolate, it is also kinetically accessible. Thiolesters are more like a ketone than an oxyester. The resonance electron delocalization is due to an overlap of sulfur *p*-orbitals with the acyl *p*-bond.

CoASH is the principal moiety for the vectorial transport of acyl and acetyl groups in synthetic and catabolic reactions. A pantothenic acid deficiency is characterized by impaired acetyl and acyl metabolism. For example, the ability to utilize fatty acids as fuels is clearly compromised in experimental pantothenic acid deficiency. There is also an increased production of short-chain fatty acids and ketone bodies, which can lead to metabolic acidosis. Dermal lesions may also occur because of impaired fatty acid metabolism (Combs, 2012).



Carboxylations

- Biotin

  Biotin is necessary for cell growth, the metabolism of fats and amino acids, as well as gluconeogenesis. There are nine known biotin-dependent enzymes: six carboxylases, two decarboxylases, and a transcarboxylase. Of these, four carboxylases have been found in tissues of humans and other mammals. Examples include (1) acetyl-CoA carboxylase (a cytosolic enzyme that catalyzes the formation of malonyl-CoA for fatty acid biosynthesis), (2) pyruvate carboxylase that forms oxalacetate for citrate formation, (3) propionyl-CoA carboxylase, and (4) β-methylcrotonyl-CoA carboxylase important in the catabolic pathway for L-leucine.

  The coenzymatic form of biotin is linked to the ε-amino group of specific lysyl residues in the family of biotin-dependent carboxylase and transcarboxylase. The flexible side arm of biotin allows for flexible movement so that an activated CO_2 moiety can be transferred to an accepting substrate. In addition to the stereochemical features, biotin's chemical role is to enhance nucleophilicity (McCormick, 2007). The reactions occur in two separate steps. ATP is required for activation in the first step. Phosphorylation of bicarbonate by ATP to form carbonyl phosphate provides an electrophilic mixed-acid anhydride, which then reacts to generate reactive N(10)-carboxylbiotinyl enzyme. This in turn sets the stage for the transfer of the activated carboxylate function to an accepting substrate, typically at a carbon with carbanion character. Further, biotin binds very tightly to the protein avidin with a dissociation constant K_d on the order of 10^{-15} M, which is one of the strongest known protein–ligand interactions.

  Biotin was discovered following a long search for factors important to the condition that causes egg white poisoning, which is associated with poor growth, alopecia, and dermatitis in animals fed raw eggs or egg whites as a primary source of dietary protein. It was eventually found that biotin-binding factors in eggs (e.g., avidin) could reduce biotin nutritional availability. Dietary biotin exists in free and protein-bound forms. The latter, biocytin (N-biotinyl-L-lysine) is released as a product of proteolysis by intestinal proteases. Cellular biocytinases next catalyze biocytin cleavage to release free biotin for reutilization.

Human biotin deficiency is rare because intestinal bacteria can produce biotin in excess of the body's daily requirements. However, several conditions can cause a deficiency, such as exposure to the binding protein, avidin, and metabolic disorders, such as a deficiency in the carboxylase synthetase enzyme that covalently links biotin onto biotin-dependent

carboxylases or biocytinase that facilitates biotin reutilization. Biotin deficiency has been postulated to be a risk factor for pregnancy complications in humans, although the extent to which this occurs is a subject of considerable debate (Dietary Reference Intakes, 2004).

- Vitamin K

  Vitamin K is a group of structurally similar, fat-soluble vitamins. The active forms of vitamin K are essential for posttranslational modifications of proteins for blood coagulation cascades (e.g., thrombin and related coagulation factors), and in metabolic pathways important to the regulation of calcification of bone. The vitamers of vitamin K are all derivatives of 2-methyl-1, 4-naphthoquinone. Plants synthesize vitamin K_1, also known as phylloquinone, phytomenadione, or phytonadione. Vitamin K_2 is the principal derivative found in animals. Bacteria in the colon convert K_1 into vitamin K_2. Vitamin K_3 (2-methyl-1,4-naphthoquinone, menadione) can also act as a vitamin K precursor if an isoprene side chain is attached. The isoprene side chain can be synthesized by bacteria or derived from the cholesterol synthesis pathway. In addition, colonic bacteria can lengthen the isoprenoid side chain of vitamin K_2 to produce vitamin K_2 derivatives that range in isopreneoid side chain length from 7 to 11 side chain residues (Suttie, 2013).

  The major function of vitamin K in animals is acting as a cofactor for enzymes that are involved in protein posttranslational chemical modifications (Suttie, 2013); specifically, the carboxylation of glutamyl residues to γ-carboxyglutamyl (Gla) residues in certain proteins important in blood coagulation and bone formation (Figure 2). The presence of two -COOH functions on the same carbon in a γ-carboxyglutamyl residue facilitates the binding of calcium ion, which in turn activates Gla-containing proteins and enzymes.

  The following human Gla-containing proteins have been characterized: (1) the blood coagulation factors II (prothrombin), VII, IX, and X, (2) the anticoagulant proteins C and S, (3) bone Gla-containing protein osteocalcin, (4) calcification-inhibiting matrix Gla protein, and (5) cell growth-regulating growth arrest-specific gene 6 protein (Gas6), which is thought to be involved in the stimulation of cell proliferation. In addition, four transmembrane Gla proteins exist for which function currently remains unknown. Gla-containing proteins are known to occur in a wide variety of vertebrates: mammals, birds, reptiles, and fish. In contrast, in plants and bacteria, vitamin K functions either as an electron acceptor in photosystem I and as a consequence is essential for photosynthesis (plants), or is important to anaerobic respiration during oxygen-independent metabolic energy production processes (bacterial anaerobic respiration).

  With respect to perturbations in vitamin K metabolism in animals, a deficiency may result from dietary insufficiency or intoxication with antagonists that act as anticoagulants, such as warfarin or coumadin. Although a dietary deficiency of

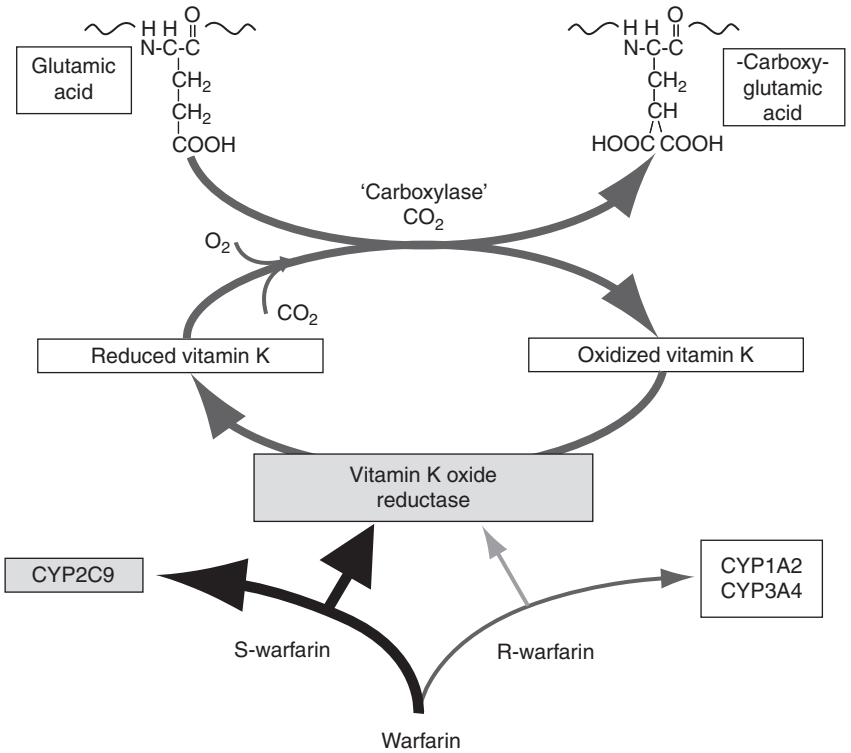


Figure 2 Vitamin K-dependent carboxylases. The vitamin K-dependent carboxylases use the oxidized form of vitamin K to convert glutamyl residues into glutamyl residues. These residues facilitate calcium binding and activation of vitamin K-dependent carboxylases to initiate hemostasis, apoptosis, bone development, arterial calcification, signal transduction, and growth control. Warfarin and coumadin derivatives inhibits the vitamin K oxidoreductase that generates the reduced vitamin K cofactor required for continuous carboxylation The cytochrome P450 (CYP) microsomal enzymes that play major roles in the oxidation of xenobiotic and endogenous compounds, such as coumadin and warfarin.

vitamin K is rare, liver disease, cystic fibrosis, or inflammatory bowel disease can increase the need for vitamin K. With respect to drug interactions, in addition to anticoagulants, other drugs associated with vitamin K deficiency include salicylates, barbiturates, and cefamandole. The reduction and subsequent reoxidation of vitamin K coupled with carboxylation of Glu is called the vitamin K cycle. Warfarin and coumadin derivatives function by inhibiting the reduction steps of the cycle. This can cause a decreased concentration of vitamin K hydroquinone in the tissues. When the carboxylation reaction is inefficient, the result is the production of clotting factors and calcium-binding proteins with inadequate Gla. Accordingly, symptoms of K_1 deficiency include anemia, bruising, and bleeding, as well as changes in bone turnover and architecture. Primary and secondary vitamin K deficiencies are also recognized to be teratogenic in humans Schaefer, 2006).

One-carbon transfer reactions and rearrangements on vicinal carbons

- Folic acid

  Deficiencies of folic acid are associated with macrocytic anemias and degenerative neurologic and developmental disorders (e.g., neural tube defects). In human populations the frequency of folic acid deficiency, either due to low dietary intakes of the vitamin or genetic polymorphisms that negatively influence its metabolism, in non-supplemented populations can be surprisingly high. Illustrative of this is that neural tube defects (presumably due in part to embryonic folate deficiencies) in Canada were reported to be reduced by close to 50% over a 10-year period following food folate fortification. The folate family of compounds is a group of heterocyclic compounds that contain 4-(pteridin-6-ylmethyl)-aminobenzoic acid conjugated with one or more L-glutamate units. The reactions that involve folic acid include the generation and utilization of formaldehyde, formimino, and methyl groups. For these conversions to occur, folic acid must be reduced in the form of tetrahydrofolic acid (THFA). The formyl, methyl, and methylene forms of THFA are utilized for purine synthesis and thymidylate synthesis (**Figure 3**), which are essential for rapid DNA synthesis and normal cell division and proliferation (e.g., cells arrest in the S-phase of the cell cycle).

  In addition, folate vitamers participate in reactions involved in the interconversion and catabolism of amino

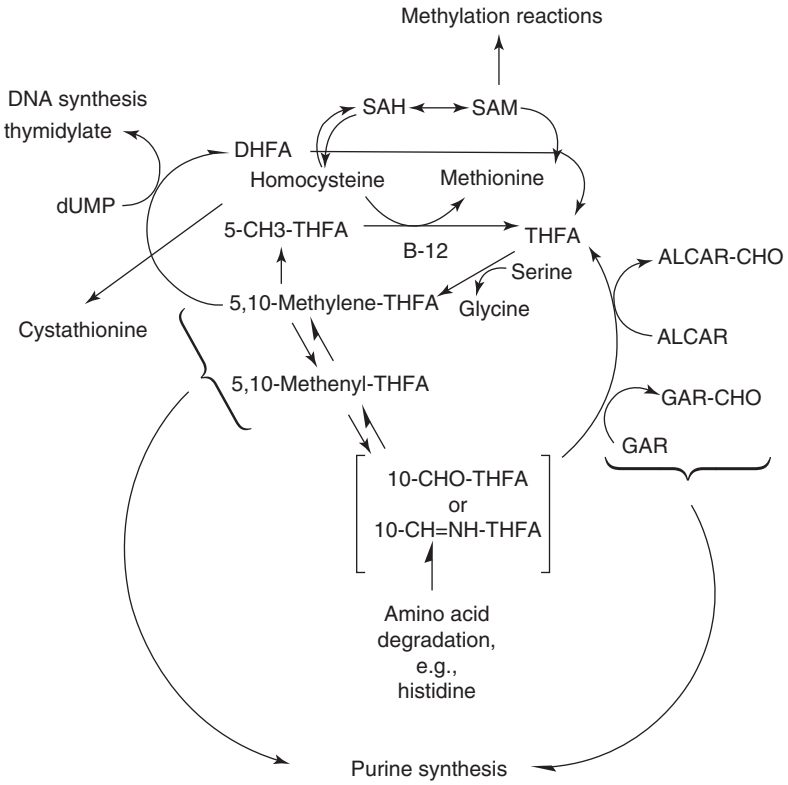

Figure 3 Folic acid, B_{12}, and single-carbon transfer reactions. Folic acid in its reduced form (THFA) and its interaction with vitamin B_{12} are essential to (1) methylation reactions (via the vitamin B_{12}-dependent methionine synthetase step), (2) DNA synthesis (the conversion of deoxyuridylate into deoxythymidylate via a single-carbon transfer from N_5, N^{10}-methylene-THFA), and (3) purine synthesis (via transfer of a single carbon from N^{10}-formyl-THFA into the purine pathway). The formyl, methanyl, and methylene forms of THFA are utilized as substrates for given reactions. Not shown in detail are reduction steps that result in the regeneration of THFA from oxidized folic acid. 5-Aminoimidazole-4-carboxamide ribonucleotide (ALCAR) and glycinamide ribonucleotide (GAR) are intermediates in the generation of purine derivatives. *S*-adenosyl methionine (SAM) is a common cosubstrate involved in methyl group transfers. It is derived from ATP and methionine. It is hydrolyzed to homocysteine and adenosine by *S*-adenosylhomocysteine hydrolase. The homocysteine is then recycled back to methionine through transfer of a methyl group from 5-methyltetrahydrofolate.

acids. The key elements of some of these reactions involve the removal of the methyl group from methyl-THFA and an irreversible transfer to methionine by the vitamin B_{12} requiring enzyme, methionine synthetase. The movement of single-carbon units from folate through methionine synthetase in the formation of methionine is also important for *S*-adenosylmethionine (SAM) formation. SAM is essential to methylation of phospholipids, and production of methylated forms of various amino acids and carbohydrates. SAM also serves as the methyl source in DNA methylation. Prolonged folic acid and vitamin B_{12} deficiencies can also result in serious neurological disorders due to the degeneration of the myelin sheath (Halsted *et al.*, 2009).

- B_{12} (Cobalamin)

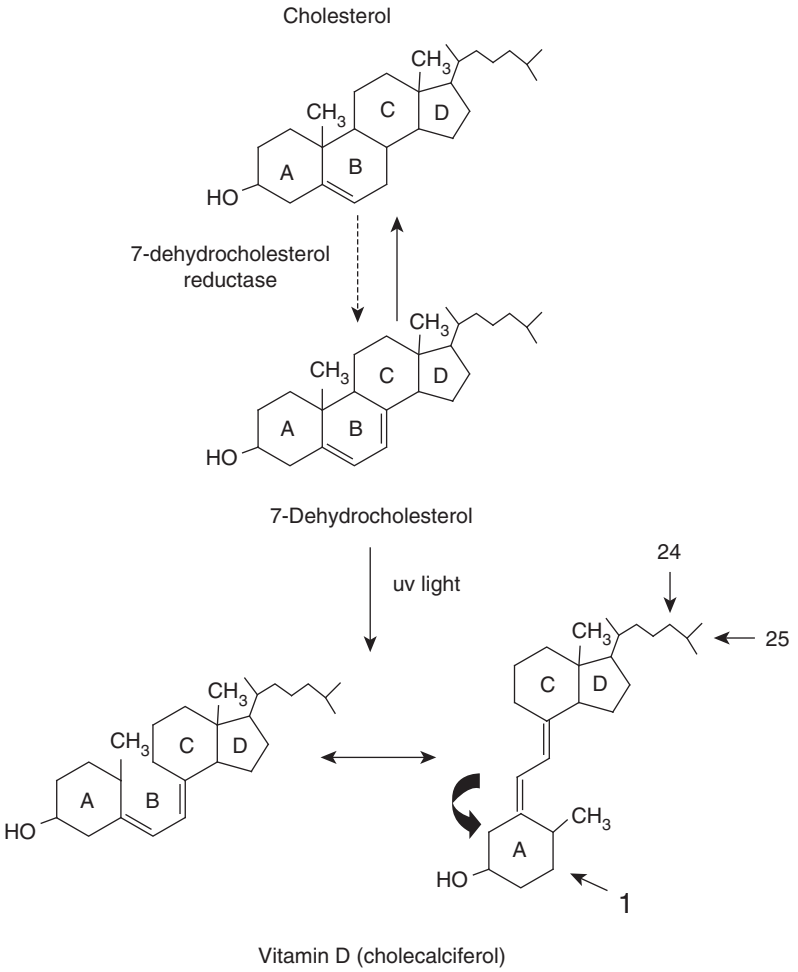
  Vitamin B_{12} consists of a porphyrin-like structure of tetrapyrrole rings with a monovalent cobalt ion at its center. There are two major cofactor forms. Methylated vitamin B_{12} serves as a cofactor for methionine synthetase. Vitamin B_{12} in the form of the adenosyl derivative catalyzes the conversion of methylmalonyl-CoA into succinyl-CoA.

  Deficiency of vitamin B_{12} leads to intracellular accumulation of homocysteine (**Figure 3**) and methylmalonic acid. The conversion of methylmalonic acid into succinate is essential to herbivores and ruminants because it facilitates the utilization of odd-chain fatty acids as potential gluconeogenic precursors. A high level of homocysteine is often associated with endothelial injury and vascular inflammation. These events are in turn associated with atherogenesis. As noted, deficiencies of both vitamin B_{12} and folic acid can produce clinical signs of macrocytic anemia and desynchronies in the growth and development owing to the importance of folic acid to purine and DNA synthesis. However, a form of vitamin B_{12} deficiency, pernicious anemia (also known as Biermer's, Addison's, or Addison–Biermer anemia) is specific to a lack of vitamin B_{12}.

  For effective absorption, vitamin B_{12} must first bind to an intrinsic factor, made in gastric parietal cells (Section Sources, Availability, and Absorption). When autoimmune destruction of gastric parietal cells occurs, it can lead to loss of parietal cells and a decreased production of intrinsic factor. Replacement of oral vitamin B_{12} does not correct the autoimmune form of B_{12} deficiency; effective treatment involves injections of B_{12}. B_{12} supplementation will reverse the signs of anemia and protect from future peripheral permanent nerve damage (a predominate feature of prolonged and severe B_{12} deficiency). When and if pernicious anemia affects the nervous system, symptoms include cognitive impairment, loss of peripheral sensations, and difficulty in navigation (ataxia). These complications are due to the degeneration of spinal cord and myelin sheet (Halsted *et al.*, 2009). Methylmalonic acid, which is elevated in vitamin B_{12} deficiency, remains in the myelin sheath and is thought to contribute to fragility. Reduced production of methionine may also be a factor, given the importance of methionine to the production of various neurotransmitters.

Cell signaling

Vitamin signaling can fall into each of the traditional endocrine categories related to cell signaling (hormonal, paracrine stimulation by cytokines, and autocrine stimulation). Dietary biofactors, such as plant secondary metabolites and vitamins, may initiate an action through transmembrane proteins (receptors) on the surface of given cells, trigger changes in the metabolism or gene expression within the cell, or cause an immediate change in an electrical charge across the plasma membrane.



- Vitamin A

  Vitamin A is directly involved in signaling events related to vision and cell differentiation, particularly epithelial cell differentiation. Vitamin A can be derived from the hydrolysis of retinyl esters to retinol and fatty acids, or cleavage of β-carotene, one of the many carotenoid pigments in plants, into retinal (Combs, 2012; Ross, 2012; Gershwin *et al.*, 2000).

  In the visual system, retinal is found in retinal rod and cone cells bound to the protein opsin as retinene. The retinene–opsin complex is called rhodopsin. When retinene interacts with light, retinene undergoes a cis–trans isomerization, which in turn changes the conformation of rhodopsin. This event initiates as series of cellular responses that alter bipolar cells from releasing neurotransmitters to the ganglion cells, which in turn alters nerve impulses in the ocular system of the central nervous system. In the presence of light, the retinal molecule changes configuration and as a result a nerve impulse is generated. The lack of vitamin A can promote a type of nyctalopia, also called night blindness, a condition that makes it difficult or impossible to see in relatively low light intensities.

  Vitamin A in the form of retinoic acid can also interact with a family of the so-called retinoic acid or retinoid signaling receptors, which are types of nuclear receptor that can act as cellular transcription factors. Retinoid binding induces conformational changes that promote recruitment of coactivators, histone acetyltransferases, and other components of the basic transcription machinery. Vitamin A deficiency influences virtually all aspects of growth and development. As noted, epithelial cells are affected in addition to the ability of immune cells to ward off infections (Ross, 2012; Gershwin *et al.*, 2000).
- Vitamin D

  Vitamin D can be synthesized endogenously from the cholesterol precursor, 7-dehydrocholesterol (Rucker, 2007). The reaction is novel because it requires exposure of skin to ultraviolet light or sunlight (270–300 nm). Peak synthesis of vitamin D occurs between 295–297 nm. Although vitamin D is commonly called a vitamin, it is not an essential dietary vitamin, because it can be synthesized in adequate amounts by most mammals exposed to sunlight. From an evolutionary perspective, photosynthesis of vitamin D by phytoplankton has existed for more than 500 million years and it is estimated that land animals have been making their own vitamin D for more than 350 million years.

Vitamin D (cholecalciferol)

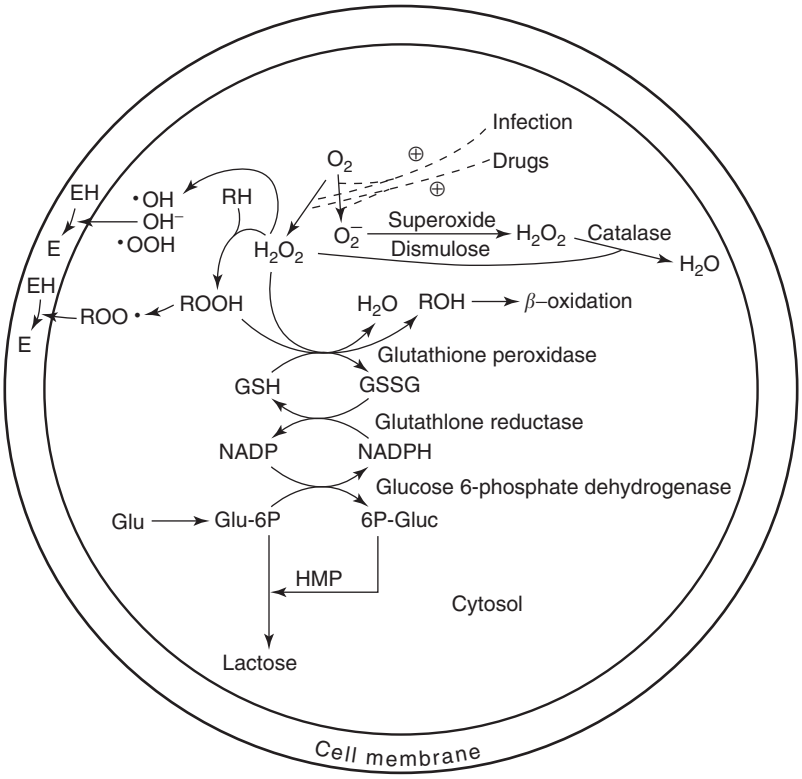
Vitamin D is a group of fat-soluble secosteroids responsible for cell signaling. One of the most active vitamin D-related secosterols is 1,25-dihydroxycholecalciferol (calcitriol). The calcitriol receptor, also known as the vitamin D receptor (VDR), is a nuclear receptor, which acts as a transcription factor. A deficiency of an active secosteroid form of vitamin D, whether due to a gene defect or a dietary deficiency (or lack of sunlight) can cause defects that range from decreased intestinal absorption of calcium and phosphate (e.g., rickets) to altering insulin and glucagon sensitivity or steps important to optimal immune function.

The production of calcitriol is normally closely regulated through feedback control and the influence of parathyroid hormone (PTH) on the activities of the 1α- and 24-OH-hydroxylases. A fall in plasma calcium triggers the release of PTH from the parathyroid gland, which stimulates 1α-hydroxylase production and leads to an increased output of calcitriol from the kidney. A separate hydroxylase that catalyzes 24,25-$(OH)_2$-D_3 production is activated under eucalcemic and hypercalcemic states.

The two major sites of action of calcitriol in relation to calcium homeostasis are bone and the intestine. Calbindin, an intestinal calcium-binding protein, is a major product synthesized in intestinal cells in response to calcitriol. Calbindin influences the movement of calcium across the intestinal cell. Binding of calcium to this protein allows the intracellular concentration of calcium to be elevated. In addition to intestinal cells, the osteoblasts of bone are another target of vitamin D metabolites and play a major role in short-term calcium homeostasis. In bones, 1,25-$(OH)_2$-D_3 is required for mineralization during skeletal growth and remodeling. VDR in bones are located in osteoblasts and progenitor cells of the bone and control the synthesis and secretion of a number of bone-specific proteins by osteoblasts, such as osteocalcin – a Gla-containing protein (Section Vitamin K), – osteopontin, collagen, and alkaline phosphatase. The actions of vitamin D metabolites are both direct (e.g., transcriptional regulation via VDR interactions) and indirect (modulation of secondary signaling pathways, e.g., protein kinase C-regulated pathways). For the most part, vitamin D metabolites attenuate the action of polypeptide hormones, such as PTH or calcitonin, which stimulates bone resorption and accretion, respectively.

VDR have also been found in a large number of cell types, ranging from skeletal muscles to cells important to immune and phagocytic functions, for example, macrophages. In pancreatic β-cells, 1, 25-$(OH)_2$-D_3 appears to be important to normal insulin secretion. Vitamin D increases insulin release from isolated perfused pancreatic cells. Moreover, vitamin D metabolites can suppress immunoglobulin production by activated B-lymphocytes. Further, T-cells are affected by vitamin D

metabolites. 1,25-$(OH)_2$-D_3 exhibits permissive or enhancing effects on T-cell suppressor activity (Gershwin *et al.*, 2000).



In children, vitamin D deficiency can result in rickets, which presents as bowing of the legs due to inefficient deposition of bone mineral. In adults, vitamin D deficiency results in osteomalacia, which presents as a poorly mineralized skeletal matrix. At the beginning of the twentieth century, it is estimated that approximately 90% of the children living at latitudes above 40 N (e.g., New York, Boston in the United States) or the Netherlands in Europe were afflicted with rickets, a bone-deforming disease. The connection to sunlight was made in the late 1980s with the discovery that 'sunbathing' was important for preventing rickets. During the past decade there has been an increasing interest in the idea that vitamin D might play a role in vascular health and this is currently an area of considerable research.

Antioxidative defense

- Vitamin E

  An antioxidant is a molecule that inhibits the oxidation of other molecules, that is, slows or inhibits the transfer of electrons or hydrogen to an oxidizing agent. This is important, because oxidation reactions can produce free radicals that, in turn, can start damaging oxidative chain reactions. Polyunsaturated lipids and proteins are often targets. Within lipid membranes, vitamin E can act as an antioxidant at a chemical (i.e., nonenzymatic) level. The intercalation of various forms of vitamin E into lipid-enriched membranes provides protection. In this regard, vitamin E vitamers in plants and animals represent one part of a complex system of antioxidants that includes glutathione, vitamin C, and enzymes, such as catalase, superoxide dismutase, and various peroxidases (**Figure 4**).

  Vitamin E is present in plants in eight different forms with largely similar antioxidant potential; nevertheless, in higher organisms α-tocopherol is preferentially retained suggesting a specific mechanism for its uptake. It also has the apparent ability to inhibit protein kinase C, 5-lipoxygenase, and phospholipase A2 and activate protein phosphatase 2A, diacylglycerol kinase, or modify the activity of certain receptors that respond to oxidants. However, more information is necessary to ascertain the exact mechanisms. As an example, oxygen-free radicals can be generated by advanced glycation end products (AGE), which are nonenzymatically glycated and oxidized proteins. Cellular interactions with AGE also influence cell signaling and the expression of specific genes (e.g., increased expression of mitogen-activated protein kinase organizer 1, which is linked to the control of several extracellular signal-regulated kinases). Given that vitamin E vitamers can influence the formation of AGE,

Integrated view of the oxidant defense system

Figure 4 Vitamin E. Vitamin E defends against abnormal lipid peroxidation at a chemical level in lipid membranes. Enzymes, such as superoxide dismutase, catalyzes superoxide radicals to hydrogen peroxide, catalase, glutathione peroxidase (catalyzes lipid and hydrogen peroxides to water or hydroxy fatty acids), and related systems for oxidant defense (generation of NADPH and reduced glutathione (GSH)) also play seminal roles.

the role of vitamin E vitamers may be indirect, in contrast to an interaction directly with specific receptors important to gene expression (Combs, 2012).

Requirements, Sources, and Assimilation

Requirements and Factors Related to Deficiency

The vitamin requirements for adult humans, as currently set by the United States and Canadian dietary reference intakes, are presented in **Table 1**. In this regard, there are two external sources of water-soluble vitamins; a dietary source that is often complemented or augmented by vitamins generated by the intestinal microbiota. Acute deficiencies can be induced under experimental conditions for most of the vitamins. Fortunately, deficiency diseases are not typically observed unless specific food sources are severely limited due to poor food distribution, exposure to antagonists, or severe economic constraints that limit access to food. Nevertheless, subclinical deficiencies can be observed when individuals consume a monotonous diet in which food variety is limited. Select genetic polymorphisms can also result in an increased need for certain vitamins. Polymorphisms can cause protein structural alterations that in turn can result in abnormal vitamin-derived cofactor binding to a given enzyme or abnormal cellular transport. In addition, disturbances of absorption (e.g., pancreatic insufficiency, biliary obstructions, alcohol, and enteropathies), antagonists (e.g., antibiotics, tannins, caffeic acid, and alcohol), or metabolic conditions (e.g., pregnancy and diabetes) can contribute to an increased need for select vitamins.

The nutritional essentiality for some of the vitamins results from an inability to synthesize the corresponding aromatic compounds that act as precursors. A good example is the lack of a shikimatic acid pathway, which is utilized in the bacteria, fungi, algae, parasites, and plants for the biosynthesis of aromatic amino acids, such as phenylalanine, tyrosine, and tryptophan. Another example is the absence or a defect in a specific component of a metabolic pathway. In some animals, the enzyme gulonolactone oxidase is absent in the pathway for glucose or galactose oxidation. If gulonolactone oxidase is missing, ascorbic acid (vitamin C) synthesis is compromised. Most animals with the exception of primates, guinea pigs, fruit-eating bats, some invertebrates, and salmonoid fish can synthesize ascorbic acid. These animals have either no gulonolactone oxidase activity or insufficient amounts for effective synthesis of ascorbic acid.

The need for niacin, vitamin A, and vitamin D in some carnivores is also worthy of comment. In animals that must be sustained on carnivorous diets, there is less capability than omnivores and herbivores to adapt to wide variations in dietary composition. In cats, the obligatory dietary requirements for niacin (NAD) and vitamin D result from the high activities of enzymes that catabolize and divert precursors of these vitamins to other compounds. As examples, many carnivores metabolize tryptophan to picolinic acid instead of quinolinic acid, which results in a decrease in NAD production (See Schema Niacin). Ineffective vitamin D synthesis in cats is due to the high activity of the 7-dehydrcholesterol (7-DHC) reductase, which converts 7-DHC into cholesterol, instead of vitamin D (See Schema Vitamin D). In contrast, the absence of enzymes required for cleavage and oxidation of carotenoids (e.g., β-carotene) can result in inefficient conversion into vitamin A (Rucker *et al.*, 2008).

Sources, Availability, and Assimilation

Vitamins in foods are usually present as highly modified derivatives. Pancreatic and intestinal cell-derived enzymes are required to initiate normal uptake in absorption. Intestinal nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins (Combs, 2012; Rucker, 2007; Said, 2011). Transport of given vitamins can be receptor mediated, occur via pericellular-related processes, passive transport (usually at high luminal concentrations), active transport (requires energy), or facilitated processes (requiring a transporter or chaperone). Some examples are given in **Figure 5**.

It is now well established that intestinal absorption of the water-soluble vitamins occurs by means of specific carrier-mediated processes. Regulation involves transcriptional and posttranscriptional mechanisms. It is also now appreciated that the large intestine also possesses specific and efficient uptake systems to absorb, in particular, a number of water-soluble vitamins that are synthesized by the gut microflora (Said, 2011). Some selected characteristic of water-soluble vitamin transporters are described in **Table 2**.

The fat-soluble vitamins, in general, are absorbed similar to lipids. As lipids, they are partitioned into liposomes and intestinal micelles in preparation for absorption. Once inside enterocytes, fat-soluble vitamins and their derivatives can be partitioned into either chylomicron or very low-density lipoprotein (VLDL) particles and transported into the lymphatic system to targeted tissues, or they can be complexed to given transporters for deliver via blood. Analogous to the water-soluble vitamins, each fat-soluble vitamin has specific and highly regulated processes that are associated with their delivery to targeted cells. For some fat-soluble vitamins, transporters that are compatible with transport in blood are also expressed, usually in the liver. As examples, after delivery of vitamins A, E, and K to the liver via chylomicron or VLDL particles, vitamin A is transported from the liver to targeted tissues by the retinol binding protein; vitamin E by α-tocopherol transfer protein or high-density lipoprotein particles and remnants; whereas vitamin K (particularly the forms made or modified in the liver) is predominately transported by VLDL-derived particles.

Although beyond the scope of this article, it is important to appreciate that at cell surfaces there are multiple transport systems for the cellular influx and efflux of compounds, such as vitamins and biofactors. Many of the transporters are within the large family of ATP-binding and dependent cassette transporters (the so-called ATP-binding cassette (ABC) transporters). Further, within the cell, vitamins undergo specific and metabolically controlled modifications before they are activated or converted into functional forms (e.g., modifications that lead to enzymatic cofactor formation or lead to compounds that interact with cell or cellular organelle receptors to initiate specific cell signals).

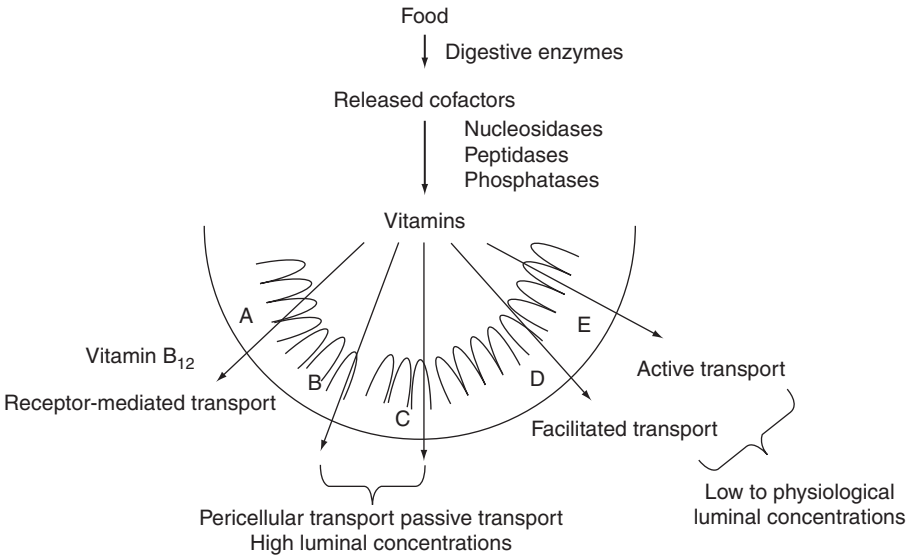


Figure 5 Vitamin absorption. Vitamins in foods are often present as cofactors or in chemically complex forms. Accordingly, pancreatic, some liver-derived (via biliary secretions) and intestinal cell-derived or microbiota-derived enzymes are required to initiate normal uptake in absorption. Nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins. Transport of given vitamins can be receptor mediated, occur via pericellular-related processes, passive transport (usually at high luminal concentrations), active transport (requires energy), or facilitated processes (requiring a transporter or chaperone).

Physiologically Important Metabolites and Biofactors in Foods

One of the most promising new areas of food- and nutrition-related research focuses on edible plant and intestinal microbiota-derived compounds that have been reported to elicit positive health effects that are in some cases 'vitamin-like.' The designations used to define such compounds include biofactors, primary metabolites, and secondary metabolites, although these designations are somewhat arbitrary. For example, primary plant and microbial metabolites are compounds that function directly in photosynthesis, respiration, and growth. In contrast, secondary metabolites are organic compounds that are not directly involved in the normal growth, development, or reproduction of a species, but their absence may result in select long-term impairments and shortened survivability.

For example, there is growing evidence that many biofactors when present at certain concentrations reduce the risk for age-related chronic diseases, such as cardiovascular disease or macular degeneration. In plants, compounds that serve as secondary metabolites have evolved to provide protective camouflage, repel predators, or facilitate electron transport and in the transformation of specific wavelengths of light into chemical energy. Much of what is known about biofactors extends from studies that were originally designed to define aspects of drug, pharmaceutical, and xenobiotic metabolism. A xenobiotic is an external chemical that a given organism does not normally produce and is either eliminated or put to a novel use. Our diets contain thousands of such compounds. With respect to health effects, epidemiological studies have shown correlations between the numerous dietary intake bioactive factors and the risk of chronic diseases (Schaefer, 2006; Shenoy *et al.*, 2011).

Table 3 lists some of the major secondary metabolites that have been studied to date, along with their putative functions (Demain and Fang, 2000). Not included are the 'nonsmall molecules,' such as derivatives of DNA, ribonucleic acid, ribosome, or polysaccharide. With regard to the discussions that follow, they are also limited, focusing primarily on secondary metabolites that influence ATP production and nutrient partitioning. These compounds are typically classified as flavonoids, flavanols, or polyphenolics. Included in the discussion are descriptions for resveratrol, quercetin, various procyanidins, hydroxytyrosol, and pyrroloquinoline quinone (Schroeter *et al.*, 2010; Shenoy *et al.*, 2011; **Figure 6**).

The authors have had constant environmental exposure to primary and secondary metabolites; thus, it is reasonable to propose that we have evolved to recognize patterns of these metabolites. One possible function of such recognition may be to set the stage, via complex cell signaling, for assimilating complex food mixtures and energy sources.

Resveratrol

Resveratrol is a stilbenoid (3,5,4′-trihydroxy-trans-stilbene; a type of natural polyphenolic compound) and a phytoalexin, a class of compounds produced by some plants when under attack by pathogens, such as bacteria or fungi. It is found predominately in purple grapes, red wine, peanuts, and some pigmented berries. In animals, at high amounts resveratrol has been reported to have biological properties that range from cardioprotection to enhanced neuronal activity. Although resveratrol was initially thought to be one of the primary protective substances associated with the so-called French Paradox, and to possess antiaging properties, recent research has failed to demonstrate an extension of lifespan in lean, genetically normal mice. Nevertheless, when administered at

Table 2 Characteristics of water-soluble vitamin intestinal transporter

Vitamin	*Transporter and receptor system(s)*	*Description*
Ascorbic acid (AA)	Transport is facilitated by both Na-dependent and Na-independent vitamin C transporter systems	Studies on the mechanism of intestinal absorption of AA indicate the involvement of an Na-dependent, carrier-mediated mechanism. In contrast, the transport of dehydro-AA occurs via Na-independent carrier-mediated mechanisms that can be competitively inhibited by hexoses. The dietary level of AA adaptively regulates AA absorption
Biotin	Transport is facilitated by an Na-dependent multivitamin transporter	In the intestine, protein-bound biotin (as biocytin) is digested by gastrointestinal proteases and peptidases to release biocytin (biotinyl-L-lysine) and biotin – short peptide conjugates. Free biotin is produced by the action of the enzyme biotinidase. An Na-dependent carrier-mediated transporter facilitates absorption. Uptake is adaptively regulated by the luminal content of biotin. The Na-dependent transporter is described as a multivitamin because of its role in the transport of pantothenate and lipoate in addition to biotin
Cobalamin (vitamin B_{12})	Receptor for the intrinsic factor(IF)/B_{12} complex; receptor for transcobalamin II	Protein-bound vitamin B_{12} is released from dietary proteins by low pH and the action of pepsin from gastric secretions. The R-proteins (haptocorrins and cobalaphilin) next bind the released B_{12}. The B_{12} is then exchanged to IF, a protein that is synthesized by gastric parietal cells. The exchange from R-proteins to IF occurs in the duodenum. A B_{12}/IF complex must be formed in order to interact with receptors on enterocytes found in the terminal ileum. Accordingly, absorption of B_{12} from food requires the normal function and presence of the stomach, exocrine pancreatic factors, IF, and the small bowel. Following absorption, vitamin B_{12} is transferred to transcobalamin II, the primary plasma transporter, which carries B_{12} to targeted cells
Folic acid	Reduced folate carriers; Proton-coupled folic acid transporter (a pH-dependent, Na -independent carrier-mediated receptor)	Dietary folate exists as mono- and polyglutamates. Folate polyglutamates are first hydrolyzed to folate monoglutamates before absorption. This digestion process occurs mainly in the proximal part of the small intestine catalyzed by folylpoly-γ-glutamate carboxypeptidase. The reduced forms of folate (e.g., tetrahydrofolic acid (THFA)) interact with a pH-dependent, Na-independent carrier-mediated receptor. THFA is eventually transferred to plasma transport proteins that have high affinity for THFA
Niacin	Proposed transporters include an acidic pH-dependent and Na-independent transporter and monocarboxylate transporters 1 (low affinity) and 2 (high affinity)	Intestinal absorption of niacin appears to involve several distinct transporters. The pH-dependent intestinal uptake of nicotinic acid is proton-coupled and involves an active carrier-mediated transport mechanism, rather than a simple diffusion, as one was believed
Pantothenic acid	A sodium-dependent multivitamin transporter	The same sodium-dependent multivitamin transporter responsible for biotin and lipoic acid transport also is responsible for pantothenic acid transport
Pyridoxine	Evidence for a pH-dependent, non-Na-dependent carrier-mediated mechanism	Regulation is sensitive to changes in vitamin B_6 intake, and appears transcriptionally mediated and linked to a protein kinase A/cAMP-dependent process
Riboflavin	Riboflavin transporter 1 (found on the luminal surface) and riboflavin transporter 3 (found on the serosal surface)	Absorption is sensitive to changes in dietary riboflavin intake
Thiamine	Thiamine-specific transporters located on the lumen and serosal surfaces of enterocytes. The transport process is pH dependent, but not Na dependent	Dietary thiamine levels adaptively regulate (at the level of transcription) intestinal thiamine uptake

pharmacologic doses (several hundred of milligrams per kilogram of diet) many investigators have reported increased telomerase activity enhancement, antiinflammatory effects, and improvements in glucose regulation in numerous rodent models. Mice treated with resveratrol have been reported to respond better than nontreated mice to oxidative stresses induced by exposure to various chemical agents. For perspective, in humans, a daily dose in the range of 300–3000 mg is often required to achieve a significant clinical response, such as bringing abnormally high levels of blood glucose back into

Table 3 Important secondary metabolites

General classifications	*Definition*	*Examples*	*Characteristics and potential health-related functions*
Alkaloids	Alkaloids are difficult to characterize because of their structural diversity. Most contain basic N atoms and are derivatives of any of the following compounds: acridine, benzylamines, colchicine, diterpenes, indoles, indolizidines, imidazole, isoquinoline, isoxazoles, oxazoles, phenyl-ethylamines, piperidine, polyamines, pyrrolizidines, pyridines, purines, quinolines, quinolizidine, quinazolines, muscarines, steroids, thiazoles, and tropanes	Adrenaline, bufoteni, caffeine, catecholamines, cathinone, cocaine, colchicine, dopamine, dimethyltryptamine, ephedrine, ergot, morphine, mescaline, nicotine, noradrenaline, pseudoephedrine, psilocybin, quinine, serotonin, and tyramine	Most alkaloids taste bitter and many are poisonous. In plants, alkaloids can act as protectants. Some animals have evolved the ability to detoxify alkaloids. Their uses range from medical applications to recreational drugs
Glycosides	A glycoside is a molecule in which a sugar is bound via a glycosidic bond. There are numerous subcategories including those described under the heading of general categories in this table	Cardiac glycosides: ouabain and digoxin; rhamnosides, such as the flavonol glycosides (azalein, eupalin, eupatolin, kaempferitrin, myricitrin, quercitrin, and rhodionin)	Many secondary metabolites are sequestered or stored in organisms as glycosides. They act through xenobiotic-sensing nuclear receptors (important to the expression of detoxification and clearance pathways) or cell-signaling systems in ways that often initiate changes in metabolism
Phenols and natural ketones including: flavonoids, flavanols, and polyphenolics	Phenolic compounds and those with flavanoid character can be formed either via the shikimate pathway, the acetate/malonate (polyketide) pathway, or the acetate/mevalonate pathway. Some may also be produced by chemical or enzymatic annulation (e.g., the condensation of tyrosine and glutamic acid to produce pyrroloquinoline quinone)	Catechin, epicatechin, hydroxytyrosol, procyanidins, pyrroloquinoline quinone, quercetin, and resveratrol	In plants, the actions and functions of phenolics and flavonoids range from colorants, ultraviolet, and ionizing radiation protectants to growth factors to antimicrobials/phytoalexins and antioxidants. In animals and humans, exposure to flavonoids, flavanols, and polyphenolics contribute to reduced mortality rates and have a number of health attributes related to improving blood pressure control, vision, inhibition of nitric oxide production, decreased platelet aggregation, and neuroprotective, among others
Phenazines	Produced mostly in bacteria, such as *Pseudomonas* spp., *Streptomyces* spp., and *Pantoea agglomerans*. The biosynthesis of phenazines branch from the shikimic acid pathway at a point subsequent to choristic acid. Chorismate-derived intermediates are brought together to form the basic phenazine scaffold. Sequential modifications result in phenazines with differing biological activities	Pyocyanin, phenazine-1-carboxylic acid, and related derivatives	Phenazines increase of bacteria survival in soil environments improves the ability to colonize; however, these compounds may have the same effects in aerobic environments, such as the lung; thereby promoting inflammation and gram-negative bacterial proliferation

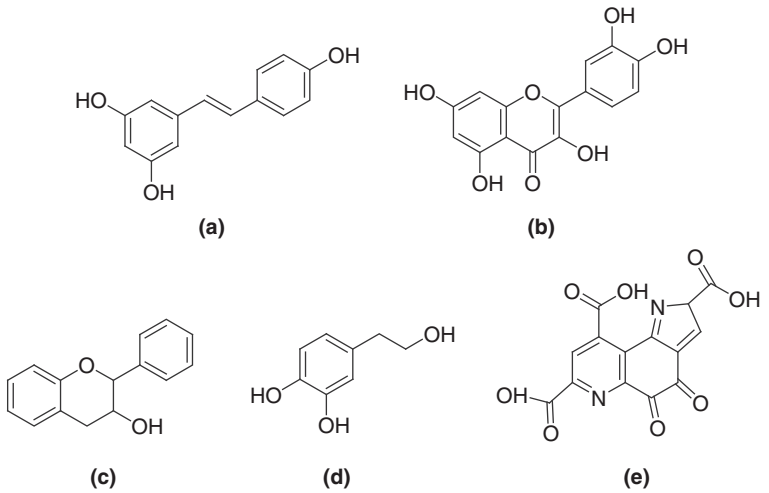

Figure 6 Biofactors important to mitochondrial metabolism and regulation. (a) Resveratrol is a stilbenoid and a phytoalexin. (b) Quercetin is a flavonoid with the basic structural characteristics of a flavanol. (c) Flavanols (the basic backbone structure is shown) include derivatives of catechin, epicatechin, and procyanidins (various condensed tannins including dimers, trimmers, and longer polymeric forms). (d) Hydroxytyrosol is a phenylethanoid, a type of phenolic phytochemical with antioxidant properties. (e) Pyrroloquinoline quinone serves as a redox cofactor in certain bacteria and also found in plant and animal tissues.

normal range. When administered orally, resveratrol appears readily absorbed; however, this is followed by extensive hepatic gluconuridation and sulfation to form resveratrol-3-O-glucuronide and resveratrol-3-sulfate. The conversion is very efficient. Less than 5 ng of nonderivatized resveratrol per milligram of blood are detected in the blood after a 25 mg oral dose in humans, even though resveratrol and its derivatives are efficiently absorbed. To achieve a clinical response in humans, microgram amounts per milliliter are required, which usually corresponds to oral intakes of 1 g or more per day.

Studies designed to elucidate resveratrol's actions have nevertheless been useful as research templates for the now hundreds of studies dealing with the role and function of biofactors in general (Shenoy *et al.*, 2011). An example is studies on resveratrol's ability to modulate cell signaling important to mitochondriogenesis. Resveratrol is capable of competitively inhibiting various phosphodiesterases, which results in an increase in cytosolic concentration of cyclic adenosine monophosphate (cAMP). cAMP in turn acts as a second messenger for the activation of major energy pathways, which result in increases in the oxidation of fatty acids, mitochondrial biogenesis, mitochondrial respiration, and gluconeogenesis. In addition, several mitochondrial enzymes are induced whose function is to aid in controlling damaging reactive oxygen species levels (e.g., catalase and mitochondrial Mn-superoxide dismutase).

Quercetin

Quercetin derivatives, derivatives of 2-(3,4-dihydroxyphenyl)-3,5,7-trihydroxy-4H-chromen-4-one, are flavonols (a subclass of the flavonoid family) found in fruits and vegetables, particularly onions and apples. Quercetin as an aglycone is not a common dietary component. Normal diets contain quercetin glycosides, which are converted into quercetin in the gastrointestinal tract (Mendoza and Burd, 2011). Mice fed quercetin have increased levels of cellular mitochondria, based on the mitochondrial DNA content and increased cytochrome c oxidase activity (a measure of mitochondriogenesis). These observations are supported by evidence of increased exercise tolerance in mice exposed to quercetin. Several studies have shown that quercetin may have antiinflammatory properties, act as an antihistamine, as well as influence induction of insulin secretion by the activation of L-type calcium channels in pancreatic β-cells (Mendoza and Burd, 2011).

The estimated intake of quercetin for humans ranges from 10 to 25 mg per day. Like resveratrol, however, substantial amounts (e.g., >100 mg quercetin per day in humans) are needed to elicit clinical changes in humans (e.g., improvements in assays designed to assess antiinflammatory or antioxidant potential). In typical studies, a dose of 500–1000 mg per day is administered.

However, many of the health claims ascribed to quercetin have been difficult to replicate, particularly those focusing on athletic performance. In this regard, a comment that applies to all exercise studies involving biofactors is that the level of prior training is often a factor, given that exercise and controlled food intake influence the mitochondrial function and measurements important to the assessment of athletic endurance (Mendoza and Burd, 2011).

Flavanols

Flavanols are another subclass of flavonoids that exist in a variety of chemical forms and derivatives. Specifically, flavan-3-ols are derivatives of flavanols that have 2-phenyl-3,4-dihydro-2H-chromen-3-ol as the functional moiety or backbone. Flavan-3-ols include the catechin, epicatechin gallate, epigallocatechin, epigallocatechin gallate, and their oligomers,

proanthocyanidins or procyanidins, theaflavins, and thearubigins. Flavanols are the predominant pigments in wine, tea, and cocoa (Schroeter *et al.*, 2010). The daily estimated intake of flavanols (both monomeric and polymeric forms) is higher than that for flavonols (i.e., compounds similar to quercetin) and intakes in the range of 100–300 mg per day are commonly reported. The consumption of flavanol-rich cocoa, chocolate, and tea has been associated with the decreased risk of some vascular diseases, including cardiac events and strokes and improvements in blood pressure. True of most biofactors, the smaller or less polymerized forms of flavanols (monomers and dimers) are more bioavailable than their larger oligomeric counterparts, such as procyanidins or highly condensed polymers, often designated as tannins.

Flavanols are thought to be able to influence the mitochondrial function both by activation and control of processes important to programed cell death, that is, apoptosis. For example, epigallocatechin-3-gallate functions as an inhibitor of certain nuclear proteins important to the control (rate) of mitochondriogenesis and apoptosis. Although a good balance is maintained between mitochondrial efficiency and orderly apoptosis in normal cells, exposure to epigallocatechin-3-gallate in cell culture appears to tip the balance toward apoptosis in certain cancer cell lines. In addition, epigallocatechin-3-gallate may have the potential to improve oxidative metabolism.

Low concentrations of epigallocatechin-3-gallate (micromoles) inhibit glucose production and also reduce the expression of genes critical to glucose production. Such events can increase lipid oxidation and improve insulin sensitivity. Analogous to the other biofactors described herein, activation of 5′-AMP-activated protein kinase (important in oxidative metabolism signaling) appears to be involved. However, it is important to note that a caveat to much of the work in this area of flavanols has been done using cell culture models, and parent compounds, rather than the metabolites that exist *in vivo*. As is true for much of the work in the area of biofactors, there is a need for studies that are conducted *in vivo* using amounts of biofactors that are within the range of dietary intakes. With respect to mechanistic studies, when possible they should be conducted with the metabolites that occur *in vivo* at physiologically relevant concentrations (Schroeter *et al.*, 2010).

Hydroxytyrosol

Olive oil contains hydroxytyrosol, a biofactor often associated with the healthful effects of consuming a Mediterranean diet, a diet characterized by a proportionally high consumption of olive oil, legumes, unrefined cereals, fruits, vegetables, and fish, but low to moderate consumption of meat and dairy products. The Mediterranean diet has been associated with a lowered incidence of cardiovascular disease and certain cancers, particularly compared with cultures wherein the consumption of meat and saturated fat predominate. Extra-virgin olive oil (produced with no chemical processing) has been identified as an important contributor to the reduced mortality associated with consuming a Mediterranean diet (Shenoy *et al.*, 2011).

In Mediterranean countries, such as Italy and Greece, dietary intake of olive oil polyphenols are estimated at approximately 10–20 mg per day with daily intakes of 25–50 ml of olive oil. Hydroxytyrosol is absorbed in a dose-dependent manner according to the phenolic content of the olive oil administered. However, similar to other sources of biofactors, typical daily doses of olive oil often do not promote changes of putative health-related markers *in vivo* (e.g., serum or plasma antioxidant activity). However, the relationship between diet and achieving an effective dose of hydroxytyrosol is complex. Although extra-virgin olive oil is the principal source of hydroxytyrosol, wine contains modest amounts of hydroxytyrosol. In addition, an interesting phenomenon is that endogenous hydroxytyrosol synthesis is promoted by alcohol consumption. Exposure to alcohol redirects pathways that normally produce dopamine to hydroxytyrosol production (Shenoy *et al.*, 2011).

Analogous to quercetin and resveratrol, hydroxytyrosol's putative biological effects include antioxidant activity and modulation of energy-related pathways. Regarding modulation of energy-related phenomenon, hydroxytyrosol has been reported to enhance endurance capacity. It also has been reported to reduce fatigue and muscle damage caused by excessive or exhaustive exercise based on data from both *in vivo* and *in vitro* studies. Hydroxytyrosol has been observed to stimulate mitochondrial fission, and increase peroxisome proliferator-activated receptor gamma coactivator 1-α (PGC-1α) expression. PGC-1α is an essential coactivator in processes important to mitochondrial fusion, enhanced complex I and II activities, and mitochondriogenesis (Shenoy *et al.*, 2011).

Pyrroloquinoline Quinone

In addition to being a plant growth factor and bacterial cofactor, pyrroloquinoline quinone (PQQ) protects the mitochondria from oxidative stress and promotes mitochondriogenesis. Recent evidence suggests that compounds like PQQ are components of interstellar dust and considered a precursor of organic materials in early life on Earth. The ubiquitous presence of PQQ suggests that there has been constant exposure to this compound throughout evolution.

Similar to resveratrol and hydroxytyrosol, PQQ can influence energy-related metabolism, albeit at relatively lower doses. The mechanism of action involves interactions with cell-signaling pathways and mitochondrial function (Rucker *et al.*, 2009). PQQ administered at a dose of 0.2–0.3 mg PQQ per kilogram in humans effects changes in antioxidant potential and indices of inflammation (e.g., plasma C-reactive protein, interleukin (IL)-6 levels). PQQ supplementation also results in significant changes in urinary metabolites consistent with enhanced mitochondria-related functions. In addition, nutritional deprivation results in a wide range of systemic responses, including growth impairment, compromised immune responsiveness, and abnormal reproductive performance in experimental animal models.

Dietary sources of PQQ include many fermented products, wine, tea, cocoa, and legumes. In animals, deficiency signs are observed at levels at or below 300 micrograms PQQ per kilogram of highly purified diets. Repletion with PQQ to

mice-fed diets devoid of the compound results in improvements in growth, mitochondrial function, and immune responsiveness. In humans, amounts of 5 or more mg PQQ per day are needed to effect changes in clinical indices, (such as antioxidant activities or C-reactive protein levels). Human dietary consumption of PQQ is estimated to be 200–400 μg PQQ per day.

Concluding Comments

Vitamins and most probably many biofactors have evolved to serve unique and complex roles: as cofactors, as signaling agents in cells, as regulators of gene expression, and as redox and free-radical quenching agents. With the possible exception of vitamin D, all recognized essential vitamins are derived solely or in part from organic food substances found only in living things. As is the case for any substance that is essential to a given function, all vitamins and perhaps some biofactors at some point in development can be viewed as limiting nutrients, the absence of which results in specific deficiency signs and symptoms. What is emerging is that biofactors and their combinations have regulatory potential and may be linked to important biological processes, which are controlled and linked in turn to cellular transporter systems, such as the solute carrier (SLC) and the ABC multispecific 'drug' transporters. Highly regulated transporter networks are by necessity linked to cell sensing and signaling networks to maintain precise homeostasis. In this regard, it should be appreciated that some of the mechanisms underlying a given process are not necessarily intuitive. For example, SLC and ABC transporters are important to both the influx and efflux of substances from cells. If a given biofactor attenuates increased transport out of cells, it may also decrease the likelihood that various toxic xenobiotics or substances accumulate within given cells or tissues. Coordinated communication allows both the systems to contribute to the overall metabolism, detoxification, antioxidant capacity, and redox capacity.

We are routinely exposed to more than 5000 known phytochemicals, particularly when a mixture of fruits and vegetables are a major part of the diet. Although current research tends to focus on single compounds and concerns may be expressed, as done by the authors, regarding the seemingly high concentrations needed for demonstrating effects of the single compounds, little is known about synergisms and complementary interactions between complex mixtures of biofactors. Future research will undoubtedly begin to address such interactions and in a broad sense better define the potential requirements or suggested intakes for functional classes of biofactors. As a final point, given that many of these compounds have characteristics that promote survival, an argument may be made that their selection over eons has reduced or resulted in less exposure to those foods with definable toxins.

Glossary

Chemigation The injection of water-soluble chemicals, such as herbicides and pesticides, through an irrigation system for application to the land using the irrigation system.

Feedback control A control system that monitors the effect on the system that it controls and modifies output accordingly; for example, a system that controls irrigation application rate based on real-time soil moisture monitoring.

Fertigation The injection of water-soluble fertilizer products through an irrigation system for application to the land using the irrigation system.

Microirrigation Microirrigation, also known as drip or trickle irrigation, is an irrigation method that drips water slowly onto plant roots, either via the soil surface or directly onto the root zone, through a system of pipes, valves, tubing, and emitters.

Partial root zone drying A potential water-saving irrigation strategy which irrigates only one side of a root system, potentially saving 50% water with no impact on yield. This is because plant water potential equilibrates with the wettest part of the soil. There is some evidence to show that this effect is not long term.

Introduction

Limited opportunities to expand the volume of global freshwaters allocated to irrigation means that advanced irrigation technologies, aiming to improve efficiency of existing systems are needed, timely, and are of paramount importance.

There is little scope for greater use of allocated global freshwaters for irrigation, due to unprecedented expansion since the 1950s, plus other multiple demands on that resource to meet higher living standards: projected as +400% (manufacturing), +140% (thermal electricity generation), and +130% (domestic use) by 2050 (OECD, 2012).

Providing for a further 2 billion people by 2050 will challenge our ability to manage and restore natural assets, including freshwaters, on which life depends (OECD, 2012). Irrigation will need to support a projected 50% increase in global food supply to feed the additional 2 billion people (Jury and Vaux, 2007).

Irrigated Areas and Volumes Abstracted

Globally, agriculture is the largest user of freshwater, with irrigation withdrawals representing approximately three-quarters (70%) of the total freshwater use (Fischer *et al.*, 2007). Of this, only-one half is estimated to reach the crop – the remainder is lost during storage, conveyance, or as subsurface drainage after application (Jury and Vaux, 2007). In many developing countries, the proportion used in agriculture is upwards of 80% of withdrawals (Turral *et al.*, 2010) highlighting the dependence on water for food crop production in rural-based economies (Knox *et al.*, 2012).

Recent food shortages and commodity price spikes have raised questions regarding food security at both global and national scales (IAASTD, 2009). In this context, securing adequate water of sufficient quantity and quality for agriculture will be essential in meeting future food demands for a growing population with increasingly diverse dietary requirements. Augmentation methods, such as rainwater harvesting, are necessary to boost freshwater supplies (see e.g., **Figure 1**), but improving the efficiency of use is of paramount importance to assist sustainable use of this resource. Agriculture sits at the interface between the environment and society, so any increase in water use will need to take into account the consequent impacts on freshwater ecosystems and the multifunctional nature and diversity of benefits that irrigated agriculture provides, not just to food production (Knox *et al.*, 2010).

The value of using freshwaters for irrigation should include not only direct benefits to the party who stands to gain from the product but also the wider ecological consequences of these decisions, and the social goals being served by the decision (Costanza *et al.*, 1997). Owing to this, there will be greater government and regulatory demands for

 doi:10.1016/B978-0-444-52512-3.00087-5

(a) (b)

environmental protection of freshwaters, adding further competition for agricultural demands.

Irrigated croplands globally have increased from approximately 100 Mha in 1950 to 275 Mha in 2000 (Lal, 2009), being twice as productive as nonirrigated croplands. However, meeting future food demand will be significantly more challenging than in the 1960s when the first Green Revolution occurred, and agricultural efficiency was generally low everywhere (Jury and Vaux, 2007). Once surface waters become fully allocated, communities turn to groundwaters with less tangible accompanying ecosystem services. The unprecedented demands on global groundwaters for food production has led to overdrafting (rate of extraction > rate of recharge), which is calculated to be as much as 163 km^3 per year, with approximately 80% of this occurring in India and China (Postel, 1999). The implications of this are that close to 500 million people are being fed by a water supply that could disappear in the near future.

Seckler *et al.* (1999) estimated that up to 25% of India's grain harvest could be in jeopardy due to declining freshwater resources. China increasingly faces water shortage and food security challenges, with the area of land irrigated in 2003 having increased 3.5 times since 1949, and 75% of its grain crop being dependent on irrigation.

Improving Irrigation Efficiency

Increases in the productivity (defined as the amount of yield per unit of land, ton ha^{-1}) of irrigated land through changes in management and improvements in efficiency offer the greatest potential for global water savings (e.g., Sadler *et al.*, 2005), because irrigated agriculture is the dominant consumptive user of water.

Seckler *et al.* (1999) estimated the average irrigation efficiency (water required for 100% yield divided by irrigation withdrawals) for 118 countries around the world in 1990 as 43%, and showed that increasing irrigation effectiveness to 70% would produce a total water saving of 944 km^3 per year and reduce the need for development of further water supplies for all sectors in 2025 by approximately 50%. In reality, when

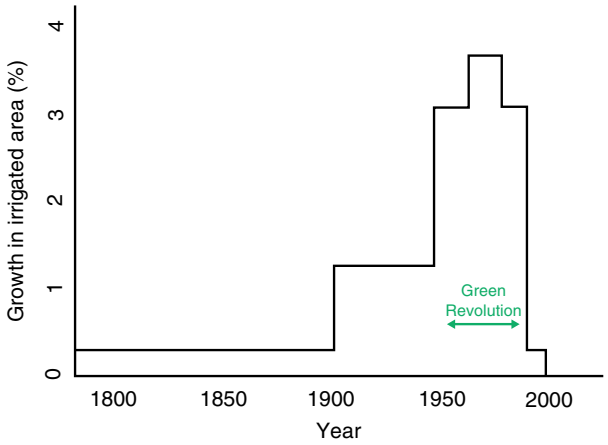

Figure 2 Reported rate of growth (% per annum) in the global irrigated area over the past 200 years. Modified from Jury, W.A., Vaux, H.J., 2007. The emerging global water crisis: Managing scarcity and conflict between water users. Advances in Agronomy 95, 1–76.

freshwater resources are limited, it is possible that saved water will be directed elsewhere to increase overall productivity. The efficiency gains enable increased food production, but do not address the need to allocate freshwaters for irrigation at a sustainable rate. Efficiency gains therefore need to be accompanied by catchment regulation to maintain a sustainable total allocation of freshwaters for irrigation (Perry, 2007).

Irrigation efficiency will become increasingly important as constraints deepen on further expansion of irrigation. There is also growing evidence that the expansion of irrigated lands, which has been steadily rising since the 1950s, has slowed as we enter the twenty-first century (**Figure 2**; Jury and Vaux, 2007).

To create efficiency gains, innovative irrigation technologies will therefore be required:

- more uniform application of water (Burt *et al.*, 1997);
- reduction of evaporation or runoff losses (Burt *et al.*, 1997);
- improvement of sprinklers by lowering the spray to reduce air losses and kinetic energy of impact (Jury and Vaux, 2007);

- improvement of irrigation scheduling and water delivery timing to reduce water losses, as well as addressing crop sensitivity at certain developmental stages (Jury and Vaux, 2007);
- use of soil monitoring and PET estimates to ensure that correct amounts of water are applied at the correct time (Jury and Vaux, 2007);
- correct tillage and field preparation to enhance infiltration and reduce evaporative losses (Wallace and Batchelor, 1997); and
- development of canal linings and other repair measures to improve the efficiency of water supply from source to field, which is estimated to average approximately 70% globally (Bos, 1985).

Summary

There is much evidence in the scientific literature which confirms that global agriculture will face a major challenge over the next few decades – supplying more food to meet increasing demands while simultaneously reducing its environmental impact (Beddington, 2010; OECD, 2012). Dwindling water supplies, an increasing frequency of droughts, and longer term uncertainties associated with a changing climate, all mean irrigated agriculture needs to do more with less. This implies both increasing water productivity (ton ha^{-1}) and raising the economic benefits attributed to irrigated production (US$ per m^3) (Monaghan *et al.*, 2013).

Farmers and agribusinesses are under pressure to reduce production inputs and costs. There are, not surprisingly, a number of emerging risks – climate change, demands for greater environmental protection, and increasing competition for water resources.

Future advances in irrigation management are likely to provide still more precision, greater automation, and increasingly ingenious and efficient irrigation options to farmers. The challenge will be to meet farmer demands for smart irrigation management in an increasingly water-constrained world.

This article therefore discusses the latest technologies designed to improve the application of water by irrigation systems both at the farm-scale and at larger regional schemes. It presents the latest advances, such as precision tools, remote sensing and web enablement. Finally, it presents an insight into future needs and trends for advanced irrigation technologies.

Technological Advances in Irrigation Application Methods

Section Overview

The traditional irrigation application methods (surface and pressurized) are now dated technologies and are at the limit of their irrigation performance under current management practices. Future gains in performance can be achieved both through improved design and through the use of advanced technologies and management, in particular the use of adaptive control. The goal is for these adaptive control systems to automatically and continuously readjust the irrigation application system to a desired performance, and account for any variability (temporal or spatial) in crop water requirements or water intake across the field.

Figure 3 Surface irrigation of sugarcane in Swaziland. Gravity fed furrow irrigation schemes are widespread in Africa although some are being converted into either pressurized sprinkler or drip irrigation to improve efficiency and manage limited water resources. Photo: J. Knox.

This section describes research directed at modernizing the application methods, and focuses on both the factors that limit performance and the simulation tools and control systems that aim to deliver the needed improvements in this performance.

Surface Irrigation

Introduction

In various types of surface irrigation (e.g., **Figure 3**), the furrows, bays (border dykes), or basins serve both as a means to convey water across the field and as a surface through which infiltration occurs. The soil infiltration characteristic more than any other factor serves to determine the level of performance or efficiency achievable from surface irrigation. The soil infiltration characteristic can vary both across the field and also from one irrigation event to the next (Walker, 1989; McClymont and Smith, 1996; Emilio *et al.*, 1997; Gillies, 2008). Khatri and Smith (2006) and Gillies (2008) identified this variability as a major physical constraint in achieving higher irrigation performance in furrow-irrigated fields.

In surface irrigation, infiltration variability causes non-uniformity in water absorption rates and furrow stream advance rates (Trout, 1990). Furrow irrigation efficiency is further compounded by the furrow-to-furrow inflow variability in both gated pipe and siphon tube operated systems (Trout and Mackey, 1988). For example, in a typical field under furrow irrigation, it is very difficult to identify one furrow that is representative of the entire field. Therefore, any field evaluation of infiltration characteristics based on measurements from only a single furrow is unlikely to give an accurate estimation of irrigation performance (Schwankl *et al.*, 2000; Langat *et al.*, 2008; Gillies, 2008).

Well-designed and managed precision surface irrigation systems thus have the potential to address both spatial and temporal variations in soil infiltration through the appropriate use of simulation, optimization, and adaptation, that is, through real-time control.

Simulation

Software packages for simulating surface irrigation hydraulics have been developed to accurately simulate the depth of water applied over the field. The two most commonly used models to date are SIRMOD (Walker, 1989) and WinSRFR (Bautista *et al.*, 2009) largely because of their ready availability. Other similar models that have been reported include BORDEV and FURDEV (Zerihun and Feyen, 1996) and that of Mailhol and Gonzalez (1993).

The software is typically based on a numerical solution of the full hydrodynamic (St. Venant) equations (see Walker and Skogerboe, 1989), or, in the case of WinSRFR, of a reduced form of these equations (the zero-inertia approximation). In all cases their accuracy is limited only by the accuracy of the input parameters, in particular the soil infiltration parameters and the resistance provided by the surface roughness of the furrow or bay (represented by the Manning's n parameter (Limerinos, 1970)).

Depths of infiltration can be calculated at a fine spacing along the length of a furrow or bay. Across the field the scale is determined by the width of the irrigation unit (furrow or bay). In either case, the prediction scale is finer than the scale at which applications can be controlled or managed. Therefore, typically an average infiltration characteristic for the entire furrow or bay is used, and this may lead to infiltration being under- and overestimated in many parts of the field (Emilio *et al.*, 1997) due to small-scale variations in the infiltration characteristics. The parameters are usually estimated from measurements (inflow, advance, flow depth, and runoff) taken during an irrigation event. Methods of estimation range from direct solution as in the two-point method of Elliott and Walker (1982) to more data intensive but robust methods involving error minimization techniques as in the volume balance-based Infiltration PARameter Model (IPARM) (Gillies and Smith, 2005; Gillies *et al.*, 2007) or the multilevel method of Walker (2005).

The analytical irrigation model of Austin and Prendergast (1997) differs from the other simulation models in that it employs an analytic solution of the kinematic equations and a simple linear infiltration function. However, its use is limited to bay irrigation of cracking clay soils, and its accuracy is inevitably limited in some field situations.

An example of simulation in the improvement of surface irrigation performance is the use of the IRRIMATE™ suite of tools (Raine and Walker, 1998; Smith *et al.*, 2005), which is now an accepted practice in the Australian cotton industry. IRRIMATE is a process of field measurement, evaluation, simulation, and optimization that uses data from a measured irrigation to evaluate the performance of that irrigation and to provide advice on the best management of future irrigation events (which in any case could be occurring under different soil conditions). The IRRIMATE system currently employs IPARM (Gillies and Smith, 2005; Gillies *et al.*, 2007) to determine the infiltration parameters from measurements of the irrigation advance and runoff. These parameters are then used in the simulation model SIRMOD in which the optimization (selection of the best or preferred irrigation flow rate and/or time to cut off) is a manual trial and error process. These are two significant limitations of the system.

The recently developed Surface Irrigation Simulation Calibration and Optimization (SISCO) model, which was applied in an evaluation of bay irrigation in the Goulburn Murray Irrigation District of Southern Australia by Smith *et al.* (2009) and Gillies *et al.* (2010), removes these limitations. As with earlier models, it employs a solution of the full hydrodynamic equations to simulate the irrigation advance and recession and provides an estimate of the irrigation performance. However, it is also self-calibrating in that it performs the inverse solution for the infiltration parameters from any of a wide selection of measured data including the irrigation advance, runoff, recession, and depth data; and optimizes the irrigation against user-defined objectives that involve some combination of the usual performance measures.

Understanding and accommodating spatial and temporal variability of infiltration in furrow irrigation is another unique feature of the SISCO model. Given some knowledge of the variation in the infiltration characteristics across a group of furrows or across a number of irrigation events (e.g., Gillies *et al.*, 2008, 2011), the model allows selection of the flow rate and time to cut off that give the best overall irrigation performance for the entire group of furrows.

Automation and control of surface irrigation

Automation and adaptive real-time control has been proposed for the management of temporal variability of infiltration characteristics (e.g., Emilio *et al.*, 1997; Mailhol and Gonzalez, 1993; Khatri and Smith, 2006). It can provide an even higher level of irrigation performance than the traditional evaluation (as demonstrated by Raine *et al.*, 1997; Smith *et al.*, 2005; Khatri and Smith, 2007) along with substantial labor savings.

Control systems used in surface irrigation can be implemented at diverse levels of sophistication and can be manual or automatic. Automation is not essential to the achievement of efficient surface irrigation; however, it does provide convenience, reduced labor requirements, and greater certainty over the control of irrigation durations.

The use of irrigation evaluations to modify future irrigations (e.g., the IRRIMATE process) is essentially an example of temporally separate feedback control where data from one event are used to control the next or future events. Real-time control as applied to surface irrigation implies that measurements taken during an irrigation event are processed and used for the modification and optimization of the same irrigation event. The real-time control system monitors the advance of water along the furrow or bay, and through a simulation process modifies the management variables (flow rate and time to cut off) accordingly before the end of that particular irrigation event. If the management variables are continually and automatically varied it is a form adaptive control.

Adaptive or real-time control of furrow irrigation potentially leads to higher irrigation efficiencies and hence substantial water savings by better matching the irrigation to the prevailing soil conditions.

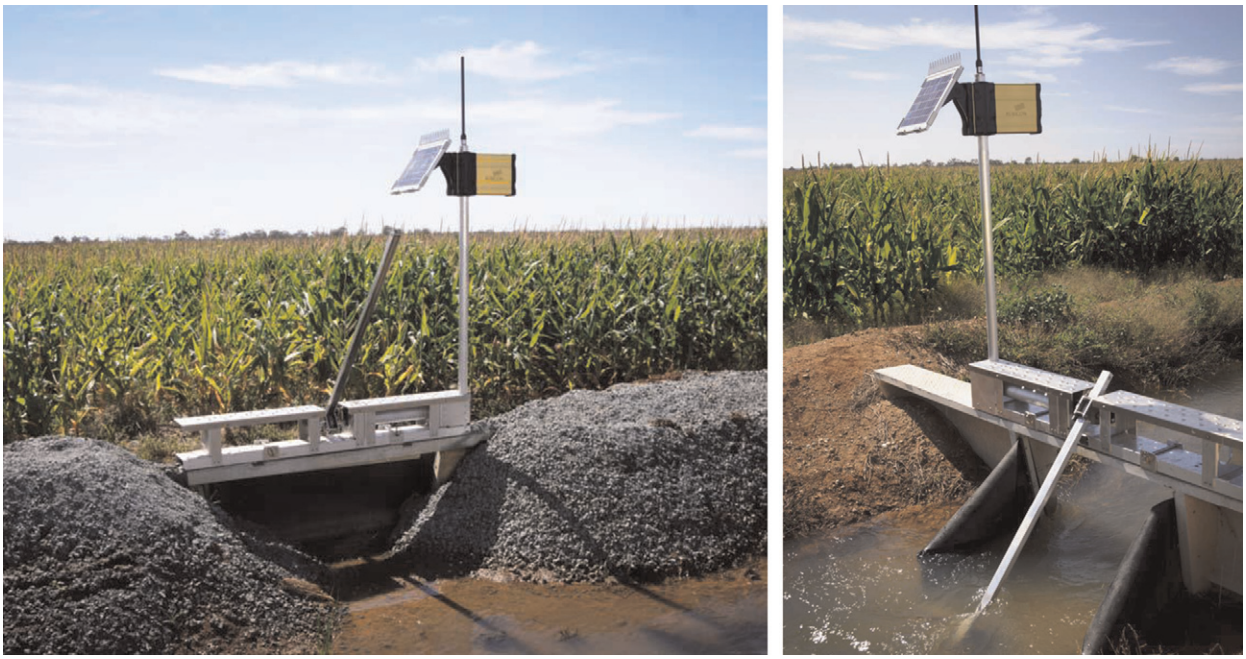

Figure 4 Rubicon farm channel actuator (left) and bay inlet actuator (right). Photos: Rubicon Water.

Automated feedback control systems have been attempted for various configurations of surface irrigation (e.g., Clemmens, 1992; Hibbs *et al.*, 1992; Humpherys, 1995a–c; Niblack and Sanchez, 2008; Uniwater, 2008). In these cases the response being sensed was the water advance down the field, where the sensing was by contact (Humpherys and Fisher, 1995) or noncontact (Lam *et al.*, 2007) means. In most cases, the control systems were able to deliver better irrigation performance (typically measured by higher application efficiencies) than the conventionally managed systems. Furrow irrigation has seen little automatic control compared with other surface irrigation techniques. Humpherys (1969) observed that border and basin irrigation systems are generally better suited to automation and control than furrow because the inflow into the bay is more easily controlled. Some previous attempts at furrow irrigation automation and control include surge flow irrigation systems (Walker, 1989; Mostafazadeh-Fard *et al.*, 2006), and conventional continuous flow (Hibbs *et al.*, 1992; Lam *et al.*, 2007).

A significant challenge in controlling surface irrigation is to obtain the data needed by the control system in sufficient time to control the irrigation. An example of this is provided by Hibbs *et al.* (1992), who developed an adaptive control system based on measurements of the outflow at the downstream end of the furrow. However, the system is impractical because in most surface irrigation systems the control decisions need to be made long before the occurrence of any outflow.

All these cases can be considered a form of adaptive control where the response being sensed is the water advance down the field and the output is the depth of water applied and the usual performance measures of efficiency and uniformity (rather than a crop response). Systems such as these account for the temporal variation in soil moisture deficits and soil hydraulic properties. Varying the management to accommodate spatial variations in the soil infiltration characteristic is usually not considered. Despite the published research, few if any of these systems have been commercialized.

Recently, Khatri and Smith (2006, 2007) established the basis for the practical real-time control of furrow irrigation, involving the following:

- continuous measurement of that inflow through inference from measurements of pressure in the supply system;
- measurement of the advance down the furrows at a single point about midway through each irrigation;
- real-time estimation of the soil moisture deficit and the current infiltration parameters from that observation of the irrigation advance; and
- real-time simulation and optimization of the irrigation for selection of the time to cut off that will give maximum performance for that irrigation.

Preliminary trials of this system, Koech (2012) show that the irrigation cutoff times predicted were shorter than those used by the farmer in irrigating the remainder of the field. This translated to reduced runoff, deep percolation, and higher application efficiencies as a direct result of real-time optimization. The system proposed has been kept simple, by using a fixed inflow and varying only cutoff time, to encourage implementation of the system. Although the real-time optimization can be operated as a manual system the greatest benefits occur when it is integrated with automation. The current phase of development of this system is the integration with the Rubicon Water FarmConnect® system (**Figure 4**). The FarmConnect® system combines short-range radio telemetry, solar power, mobile telecommunications, and cloud software on the internet to automate and remotely control surface irrigation.

In all these systems, the focus is on the control of the individual irrigation event. Although this is an important aspect to improve precision of surface irrigation delivery it is not

Figure 5 Uniform center pivot irrigation on a sugarcane crop (left) (Photo: J. Knox), and variable rate center pivot irrigation for dairy pasture (right). Photo: C.B. Hedley.

sufficient. These systems require comprehensive decision support to provide the seasonal water management that will deliver maximum water use efficiency.

Sprinkler Systems

Sprinkler or 'overhead' irrigation systems deliver water to the plant from above, and may be solid set, motorized with a boom with sprinklers attached, or hand moved, for example, rain guns. In comparison to surface irrigation systems, these systems commonly require a power source to move, and provide greater control of the applied water depths and position (see Figures 5 and 6).

Sprinkler pattern simulation

Prediction of how adjacent sprinklers overlap to give the pattern of application is essential to the design of effective sprinkler irrigation systems. In its simplest form it involves the overlapping of known patterns such as in the package SpacePro (Cape, 1998) to select the nozzle size and spacing for a given application. Here the objective is to maximize the uniformity of applied depths. It relies on knowledge of the sprinkler patterns for the given nozzle, pressure, and height above ground. Wind effects are typically ignored and the answer is relatively insensitive to uncertainties in the individual sprinkler pattern used in the analysis (Christiansen, 1941).

Simulation of sprinkler distribution patterns can not only provide input data for use in models such as SpacePro but also the basis for decision-support models for sprinkler systems in the development and application of optimum irrigation management strategies. Central to an accurate simulation of sprinkler distribution patterns is the prediction of the impact of wind (speed and direction) on the overlapped pattern. In general, higher wind speeds lengthen the sprinkler distribution pattern downwind, shorten the distribution pattern upwind, and narrow the distribution pattern normal to the wind direction (Figure 7; Shull and Dylla, 1976). Greater overlap of adjacent sprinkler patterns is thus required to obtain acceptable uniformity.

Figure 6 Overhead irrigation on onions using a mobile hosereel fitted with a boom. These methods are used on high value crops on light soils where small, frequent applications help to avoid soil and crop damage. Photo: J. Knox.

Simulation of sprinkler irrigation distribution patterns in windy conditions has evolved significantly over the past two decades. Two major approaches have been used: a deterministic approach, which applies traditional ballistic theory to calculate the flight trajectories of individual water droplets; and empirical methods, which involve extrapolation from measured sprinkler distribution patterns for various wind speeds and directions for the same nozzle, pressure, and trajectory angle.

An example of the empirical approach is the work of Richards and Weatherhead (1993) and Al-Naeem (1993), both of whom used measured wind-affected patterns to determine six empirical factors that are then used to adjust any no-wind pattern for that sprinkler to deal with the effects of wind. This same approach was extended in the TRAVGUN model of Smith *et al.* (2008), which used field-measured transects of applied depths from passes of a traveling irrigator first to calculate the no-wind sprinkler pattern and second to determine the six factors (Figure 8). Output from the model is

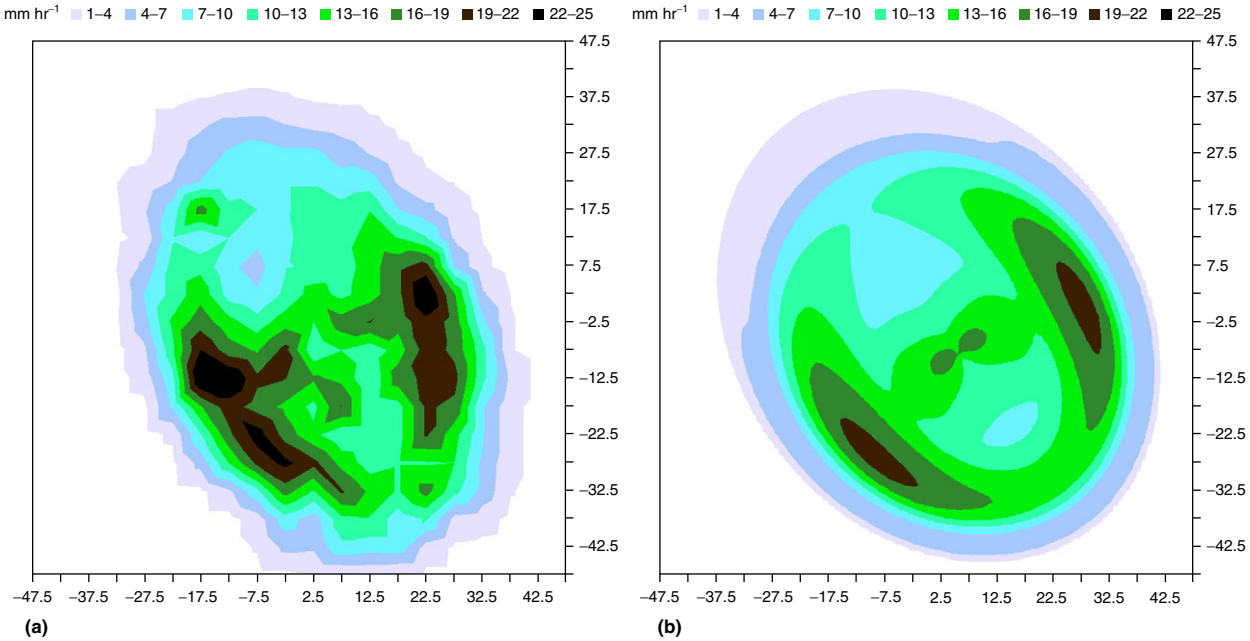

Figure 7 (a) Measured spray pattern for a rain gun sprinkler with a wind speed of 3.58 m s^{-1} (left) and (b) predicted spray pattern for a rain gun sprinkler with a wind speed of 3.58 m s^{-1}. Figure 8 Fit of the TRAVGUN model to a wind affected transect, following calibration. Reproduced from Smith, R.J., Gillies, M.H., Newell, G., Foley, J.P., 2008. A decision support model for travelling gun irrigation machines. Biosystems Engineering 100 (1), 126–136.

an estimate of the uniformity of applications for any selected wetted sector angle, lane spacing, travel direction, and wind speed and direction. The user can change the various operating parameters such as the lane spacing and sector angle to identify the optimum values for those parameters.

An advance on this notion was reported by Ghinassi (2010), where the performance of a traveling gun sprinkler is maximized by real-time variation of pressure, travel speed, wetting angle, and speed of rotation.

The SIRIAS model (Carrion *et al.*, 2001; Montero *et al.*, 2001) reflects the latest thinking in simulation using sprinkler droplet ballistics. To simulate the wind-affected pattern for a single sprinkler, SIRIAS requires a radial leg pattern measured in still air (for the given sprinkler, nozzle height, and pressure). The model uses an inverse solution to determine the droplet size distribution that would give that sprinkler pattern and then uses that distribution in the prediction of the wind-affected pattern. It has been validated for a wide range of nozzles and configurations (e.g., Montero *et al.*, 2001). The patterns predicted by SIRIAS can then be used in packages such as SpacePro to determine the overlap patterns for whole systems.

For the large mobile center pivot and lateral move systems, models that predict sprinkler patterns to estimate the uniformity of applications along the machine provide an alternative simpler method to field trials using large numbers of catch cans. However, field trials add value as they also assess machine maintenance issues, such as blocked sprinklers and hoses. Examples of this type of model are those of Smith (1989) and Thompson *et al.* (2000). Both used a similar statistical description of the droplet size distribution and combined the ballistic model with the overlap along the machine and aggregation of the pattern in the travel direction. An alternative approach was used in the mBOSS model of Foley (2011), who applied the overlap and aggregation to wind-affected patterns imported from SIRIAS.

Ballistic models typically assume that the jet from the nozzle breaks up into the assumed drop size distribution instantaneously or at some defined distance from the nozzle. In either case drag coefficients are modified in a calibration process designed to make the measured and predicted sprinkler patterns match. In an attempt to overcome this deficiency, Grose *et al.* (1998) used a three-dimensional two-phase plume, which consisted of modeling the interaction of the jet with the surrounding air, simulating the separation of the jet into individual droplets. However, this approach has not gained any acceptance.

Unless the break-up of the stream can be predicted from the fundamental fluid mechanics as attempted by Grose *et al.* (1998), any ballistic model requires a droplet size distribution for the particular nozzle type and size, and pressure to be used in the simulation. Obtaining these data is still relatively difficult, time consuming, and expensive.

In all the above models, the usual purpose is estimation of the uniformity of applications and the selection of appropriate nozzles and nozzle spacing. Although their accuracy is limited primarily by the accuracy of the ballistic models (including the use of time and vertically averaged wind speeds and directions), they are sufficiently accurate for research and design purposes. However, none are sufficiently accurate to predict applications at particular points in an irrigated field with confidence; hence they are not suitable for use in a farming decision support system for precision irrigation.

To counter the adverse effect of wind on sprinkler patterns, Ozaki (1999) developed a prototype robotic self-traveling sprinkler system that controls the nozzle sector and trajectory angles and the water supply instantaneously in response to windy conditions to minimize the distortion of the sprinkler pattern by wind and the amount of wasted water.

Spatially varied applications – Center Pivot and Lateral Move Machines

The development of mobile sprinkler systems has provided a level of convenience and efficiency as well as the greatest potential for uniform applications, although they need to be well designed and maintained to achieve this potential. For example, in a study of 39 machines, Foley (2011) showed that less than one-third were operating to specification. In addition these machines are readily adaptable to deliver spatially varied applications.

The ultimate performance from these types of machine occurs through the adoption of low-energy precision application (LEPA) technology (Lyle and Bordovsky, 1981, 1983). The LEPA system involves the use of very low pressure sprays or bubblers located just above the soil surface on the end of long drop tubes. Efficiency is improved through the reduction of spray drift and canopy interception and evaporation. Spatial uniformity is also higher than for machines fitted with conventional sprinklers.

Research into precision irrigation sprinkler systems was initiated in the USA in the early 1990s. Initially this work focused on the modification of center pivot and lateral move irrigation machines to apply spatially varied applications of water and nitrogen (Evans *et al.*, 1996; Duke *et al.*, 1997; Heermann *et al.*, 1997; Sadler *et al.*, 1997, 2000; Camp and Sadler, 1998; Camp *et al.*, 1998; King and Wall, 1998), with the system control often based on stored databases of spatially referenced data. Readers are referred to Camp *et al.* (2006) and Evans and King (2012) for comprehensive reviews of research undertaken in this field. More recently, the emphasis has shifted to the purpose and performance of spatially varied irrigations. Examples of this work include King *et al.* (2005), Sadler *et al.* (2005), Camp *et al.* (2006), Chavez *et al.* (2006), and Dukes and Perry (2006). Perry *et al.* (2003) showed substantial amounts of water conservation for center pivots, and later Han *et al.* (2009) developed and tested equipment and software for variable rate irrigation (VRI) application of water using a lateral move irrigation system.

An interesting use of a system designed for spatially varied applications was provided by Chavez *et al.* (2010). In this case, the spatially variable capacity was used to compensate for nonuniformity inherent in the irrigation applications from the machine by providing greater uniformity.

Various technologies have been used to deliver VRI applications, including

- multiple discrete fixed-rate application devices operated in combination to provide a range of application depths (see McCann *et al.*, 1997; Camp and Sadler, 1994);

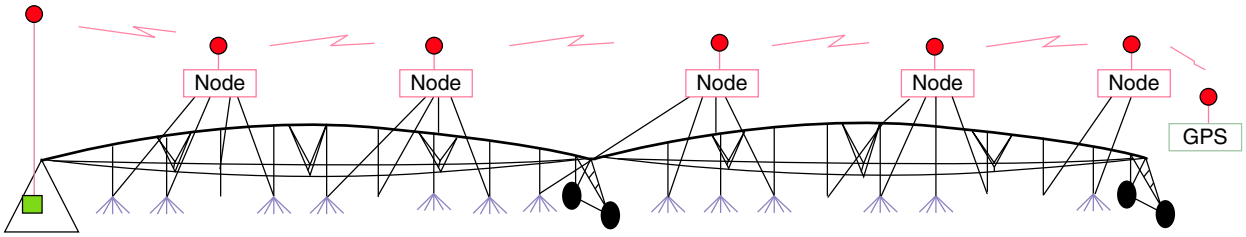

Figure 9 Schematic diagram of individual sprinkler control on a center pivot using GPS and wireless node technology (Available at: www.precisionirrigation.co.nz).

(a) (b)

Figure 10 (a) Drip irrigation used for pasture establishment in South Australia. (b) Taps control water supply to the drip tape installed at 0.2 m depth, with pressure compensating emitters at 0.4 m spacing releasing water at 1 l h^{-1}. Photos: L. Finger.

- flow interruption to fixed-rate devices to provide a range of application depths that depend on pulse frequency (see Evans and Harting, 1999); or
- variable-aperture sprinklers with time-proportional control (see King and Kincaid, 2004; King *et al.*, 1997).

Research to date has resulted in the development of prototype systems for variable rate application, with increasing commercial uptake of these products in the past few years. Appropriate decision-support systems, particularly those that incorporate the outputs from real-time monitoring technologies have not reached an equivalent stage of development. Evans *et al.* (1996) acknowledged that the greatest difficulty faced in the implementation of spatially varied irrigation is associated with determining appropriate prescriptions for the application of water and nutrients. This issue is discussed further in Section Technological Advances In Irrigation Management.

Examples of commercial systems for control of variable applications from center pivot machines are the Farmscan 7000 VRI system developed in Australia and a similar system developed in New Zealand by Precision Irrigation (Precision Irrigation, 2014). The New Zealand system was released into the market in 2008, and incorporates individual sprinkler control using wireless nodes and GPS technology (**Figure 9**).

Microirrigation Systems

Microirrigation systems are typically designed to wet only the soil zone occupied by plant roots and to maintain this at or near an optimum moisture level, using emitters spaced along drip lines. The obvious advantages of microirrigation include a smaller wetted surface area, reduced evaporation from the soil surface, reduced weed growth, and potentially improved water application uniformity within the crop root zone by better control over the location and volume of application (see e.g., **Figure 10**).

A particular benefit of microirrigation (also known as drip or trickle) is the ability to apply small amounts of water at short intervals. This provides scope to maintain the soil at a specified moisture content for part or all of the season and hence the opportunity for increased effectiveness of rainfall during the irrigation season. However, the low soil moisture

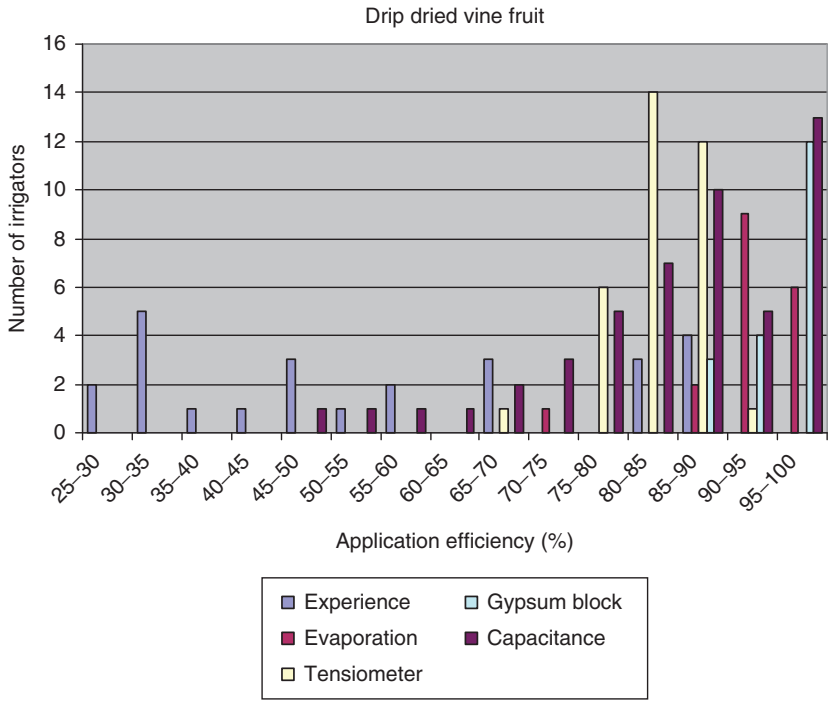

Figure 11 Application efficiencies varying with the method of scheduling irrigations for drip-irrigated vines in the Sunraysia region of Victoria, Australia. Reproduced from Schache, M., 2011. Identifying best management practice through irrigation benchmarking: Would you like probes with your drippers? In: Irrigation Australia, 2011 Irrigation & Drainage Conference, Launceston, Tasmania. Mascot, NSW, Sydney: Irrigation Australia Limited.

deficits maintained under such systems also limit opportunities for any excess rainfall to be stored in the soil. This can reduce the amount of effective rainfall and exacerbate runoff and nutrient leaching.

The potential efficiency of microirrigation systems is often quoted as being greater than 90%. Losses of water in microirrigation systems occur principally through evaporation from the soil surface, surface runoff, and deep drainage. Evaporation losses are generally small due to the limited wetted surface area and the absence of ponded surface water due to the low discharge rates. The application of water usually occurs beneath the crop canopy, either directly onto or beneath the soil surface, further reducing the potential for evaporative loss. Runoff losses are also usually small due to the low application rates. However, as with all irrigation systems, the ability to achieve high levels of efficiency is more a function of the management of the system rather than some inherent property of the system. For example, Shannon *et al.* (1996) found that drip irrigation application efficiencies under commercial conditions in the Bundaberg area ranged from 30% to 90%. Given the nature of the system, these losses were most likely from overirrigation and deep percolation. Similarly, Schache (2011) found application efficiencies of drip-irrigated vineyards in the Sunraysia region of Southern Australia to range from 25% to 100% (**Figure 11**). In this case, the identified causal factor was the method used for irrigation scheduling, with grower experience (subjective approaches) faring worst when compared with more scientific (objective) methods. Similar experiences were also observed in drip-irrigated crops under supplemental irrigation conditions (Knox and Weatherhead, 2005).

Placement of the drip lines is an important consideration in achieving high efficiencies. For example, Henderson *et al.* (2008) demonstrated a 25% gain in efficiency when drip lines were placed adjacent to each row of broccoli rather than between every second row.

Dominant causes of nonuniform applications under microirrigation systems are pressure variations along the lateral pipelines, variability in the emitters occurring during manufacture, and blockage of the emitters. Extensive evaluations of the uniformities of applications from microirrigation systems have been conducted in the USA (e.g., Hanson *et al.*, 1995) using mobile field laboratories. These have shown that emission uniformities are less than desirable with commercial systems commonly operating with an emission uniformity (E_u) of less than 80%. This is supported by Australian data from McClymont *et al.* (2009) and Hornbuckle *et al.* (2009), who reported distribution uniformities as low as 32% from a sample of drip-irrigated vineyards in Southern Australia. These observations highlight the need for improved design and in-field evaluation, diagnosis, and correction of microirrigation systems if their potential for precision irrigation is to be realized.

Systems for recording and reporting the results of performance evaluations of microirrigation systems are available, for example, Hornbuckle *et al.* (2009). However, these do not provide diagnostic capability and cannot be readily integrated with the software used for system management.

Microirrigation systems also have greater potential for accurate irrigation delivery than other systems. They are easily controlled and are commonly automated on a time, soil moisture, or time–temperature basis (e.g., Phene and Howell,

1984; Meron *et al.*, 1996; Dukes and Scholberg, 2004; Wanjura *et al.*, 2004; Evett *et al.*, 2006). They also lend themselves to adaptive control and have the potential to apply spatially variable applications at a range of scales from individual laterals to individual emitters. Variable rate-controllers that respond to real-time sensing and decision making are particularly applicable to microirrigation systems. They have not been used to apply water variably down an individual lateral or drip line, and would require additional modification for this to occur.

Research into precision irrigation for microirrigation systems has been undertaken primarily in horticultural crops including viticulture (Ooi *et al.*, 2008; Capraro *et al.*, 2008a,b) and fruit tree orchards (Coates *et al.*, 2004; Uniwater, 2008; Adhikari *et al.*, 2008).

Capraro *et al.* (2008a,b) utilized closed-loop irrigation control systems with moisture measurements in the root zones to maintain the soil moisture level around a set value. Regulated deficit irrigation (RDI) strategies were incorporated within the irrigation control system to achieve particular quality targets, that is, the enological quality of the grapes.

Coates *et al.* (2004, 2005, 2006) focused their efforts on the development of a spatially variable microsprinkler system that would allow for management of individual trees in an orchard. More specifically, the objective was to supply water and dissolved chemical fertilizers differentially to one or more individual trees fed by a single microsprinkler drip line.

Preliminary results show that spatially variable management at this scale is possible. Another example of sensor-based control of spatially varied applications from a microsprinkler system is provided by Torre-Neto *et al.* (2000).

More recently, Ooi *et al.* (2008) developed and tested an automated irrigation system for microirrigation. Two irrigation controllers – a soil-moisture-based controller and an ET-based controller – were integrated into a wirelessly networked irrigation control system in an apple orchard and a commercial vineyard. Results have shown that automated irrigation using closed-loop control systems improved water productivity by 73% compared with manual irrigation (Uniwater, 2008). These results demonstrate the potential of closed-loop irrigation control for irrigators at the lower end of the spectrum to 'leapfrog' rapidly to the upper end of the efficiency spectrum. For those irrigators already at the upper end of the spectrum, adoption of the technology would lead to substantial labor and time savings.

Technological Advances in Irrigation Management

Section Overview

This section covers the following aspects:

- advances in irrigation scheduling,
- soil moisture mapping,
- wireless sensor networks (WSNs), and
- precision irrigation management.

The technological advances in irrigation systems described in Section Technological Advances in Irrigation Application Methods must be accompanied by state-of-the-art decision support tools to determine when to turn on the irrigator and how much irrigation to apply; aiming to maximize any benefits gained from the investment in new technology. Decision-support tools either evolve alongside equipment development because the new equipment provides new and enabling methods for optimizing irrigation timing, placement, and amounts, or they may develop independently and be appropriate for use with a range of different types of irrigation systems.

Advanced irrigation scheduling (Section Section Overview) therefore aims for accurate placement of optimized amounts of irrigation at critical times. This, in turn, is primarily determined by crop water demand and soil moisture supply; and new sensor technologies are being used to define crop demand and soil moisture supply at high spatial and temporal resolution (Greenwood *et al.*, 2010). Knowledge of daily crop water demand is useful, but monitoring soil moisture supply to crop provides a predictive tool for scheduling. Section Advances in Irrigation Scheduling discusses these latest developments in soil moisture mapping; Section Soil Moisture Mapping describes methods to update static maps at regular time intervals.

Recent WSN technological advances and their commercial availability provide the means for site-specific monitoring to inform irrigation management decisions. These technological advances include smart integration of sensors, wireless nodes (for communication), internet- and cellular-enabled transfer, and processing and reporting protocols. A specific example, the sensor web enablement (SWE), an initiative of the Open Geospatial Consortium (OGC) will be discussed in Section Wireless Sensor Networks.

The term 'precision irrigation' reflects the precision agriculture concept, applying GPS with sensors to prescribe inputs in the right place, at the right time, and in the right amount. Precision agriculture addresses in-field variability, largely ignored until the 1980s, and new GPS-enabled technologies are enabling precise irrigation management tools, which will be discussed in Section Wireless Sensor Networks.

Advances in Irrigation Scheduling

Designers typically plan for the peak flow rate of a new irrigation system to meet the seasonal crop water requirements for the area to be irrigated plus any freshwater allocation requirements. Once in place, appropriate scheduling tools are then used to assess seasonal changes to daily evapotranspiration (ET) demands from specific crops, and irrigation is then scheduled accordingly.

Advanced technologies for assessing regional ET losses include remote sensing by satellite or airborne scanners (e.g., Gonzalez-Dugo *et al.*, 2006). Multispectral satellites, such as advanced very high resolution radiometer, moderate resolution imaging spectroradiometer (MODIS), and Landsat TM (Thematic Mapper), have been used since the 1970s to estimate ET. These systems are generally limited by their spatial (30 m–1 km pixel) and spectral (5–36 band) resolutions. However, maturation of imaging spectrometry technology combined with greater availability of airborne imaging spectrometer data present new opportunities for improved accuracy of ET estimates by airborne remote

sensing. These researchers tested the 'gold standard' of airborne imaging spectroscopy, NASA's airborne visible/infrared imaging spectrometer, which has 224 spectral bands at 10-nm intervals, and concluded that imaging spectrometers are suitable for determining ET and understanding associated physiological processes, although they are limited by spatial extent, and at present are most appropriate for regional estimates rather than site (field)-based estimates.

Site-specific irrigation scheduling is frequently based on soil water balance models that determine a daily soil moisture deficit using soil, crop, climate, and latitude inputs (Allen *et al.*, 1998), with a modeled daily ET value. A critical soil moisture deficit is used for timing irrigation events. Such traditional modeling tools are very useful but do not easily address commonly encountered within-field variability, and cannot easily account for factors such as ponding due to soil compaction, high water tables, variable crop growth due to shading, etc. Advanced scheduling tools need to address within-site variability due to these factors, that is, topographic relief, short-range changes in soil depth, texture and moisture storage capability and management effects including tillage, fertility, pests, and various irrigation system characteristics (Sadler *et al.*, 2005; Green *et al.*, 2006; De Jonge *et al.*, 2007; Evans *et al.*, 2012) and technologies are emerging to address the challenge (e.g., Peters and Evett, 2007, 2008).

Site-specific crop stress measurements (Green *et al.*, 2006; Peters and Evett, 2007, 2008) have been trialed for improved irrigation scheduling. Peters and Evett (2008) used a 'temperature-time-threshold method.' Crop leaf temperature is used as an indicator of crop stress, which is measured on a fully automated center-pivot irrigation system, where infrared thermocouple thermometers are attached to the trusses of the pivot. A field datalogger is accessed once a day to assess whether canopy temperature is above threshold level. Another novel method determines time for irrigation from crop stress assessed indirectly through soil moisture measurements. Onset of crop stress is indicated by a reduced apparent daily crop water uptake (Thompson *et al.*, 2007).

Soil moisture monitoring tools for triggering irrigation are perhaps the most widely used and most important tools for irrigation scheduling (Fang *et al.*, 2007) and a range of new improved sensors for monitoring soil water are now available (Cardenas-Lailhacar *et al.*, 2010). Improved accuracy of soil moisture sensors is obtained by site-specific calibration and ensuring good soil contact on installation (Greenwood *et al.*, 2010). Recent advances have been made to link soil moisture monitoring sites automatically to software decision tools linked to irrigation systems. Blonquist *et al.* (2006) installed a soil moisture sensor (time domain transmission) to log volumetric soil water content compared with an irrigation threshold, and connected this to a solenoid valve on the irrigation line supplying water to the irrigation system. This system applied 53% less water than under the conventional method. Kim *et al.* (2009) also linked soil moisture monitoring equipment to software control of a site-specific precision linear-move sprinkler irrigation system.

Other technologies have been developed for other methods of irrigation application. In surface irrigation schemes, where farmers receive a fixed amount of water during a fixed period, site-specific scheduling is limited. Here regional scheduling tools become important; and GIS-integrated tools have been developed for equitable irrigation supply to account for variability in soil and crop conditions, unreliable intake of water into the main canal, absence of storage reservoirs, and uneven distributions of water into tertiary canals (Rowshon *et al.*, 2009). The GIS tool links field irrigation demand predictions and then simulates and recommends optimal irrigation supply strategies in the Tanjung Karang Irrigation Scheme for rice growers in Malaysia.

Australian researchers have developed an integrated model for simulating border-check irrigation of dairy pastures that combines a biophysical model of the soil–plant–climate interaction with a hydraulic irrigation model, which models infiltration and movement of water through the soil matrix (Douglas *et al.*, 2010). This model was used to assess how pasture production varied with irrigation management, such as irrigation duration, to improve overall scheduling of irrigation within the scheme.

An Australian review of software tools for on-farm water management (Inman-Bamber and Attard, 2005) lists a number of irrigation scheduling software packages that are increasingly being integrated into irrigation control via web and cellular control systems. Hornbuckle *et al.* (2009) describes a remote sensing method for assessing within-field crop health variations (using NDVI) and links this to reference ET values from nearby weather stations to provide field-specific scheduling information. This crop coefficient derivation process uses a short message service (SMS) to provide information through a simple mobile phone text message service to irrigators on a daily basis. Such technologies enable real-time adaptive control systems for irrigation application (Smith *et al.*, 2010). Adaptive control means that scheduling parameters are based on feedback from the process (Fig. Smith *et al.*, 2010, p. 62) aiming for continued system improvements.

These scheduling methods assess crop and soil status, as well as other management effects – regional and some site specific – to improve scheduling tools. Site-specific measurements are obviously preferable and the next section explains how mapping tools can be combined with site-specific measurements to (1) optimize positioning of the sensors and (2) provide a map of soil or crop condition to add further refinement to decision support tools and technologies for irrigation scheduling.

Soil Moisture Mapping

Recent technological advances in GPS-enabled proximal (ground-based) sensing methods are providing rapid affordable mapping methods of land, soil, and crops to inform irrigation management decisions. For example, electromagnetic induction (EM) surveys typically use very accurate positioning equipment (e.g., real-time kinematic differential GPS, RTK-DGPS), quantifying soil spatial variability at resolutions of <10 m, and simultaneously providing a digital elevation map (DEM) with an accuracy of <0.1 m.

The EM sensor measures soil apparent electrical conductivity (EC) which is influenced by soil texture and moisture in nonsaline soils (e.g., Sudduth *et al.*, 2005; Brevik *et al.*, 2006). Soil EM maps provide the basis for targeted soil sampling

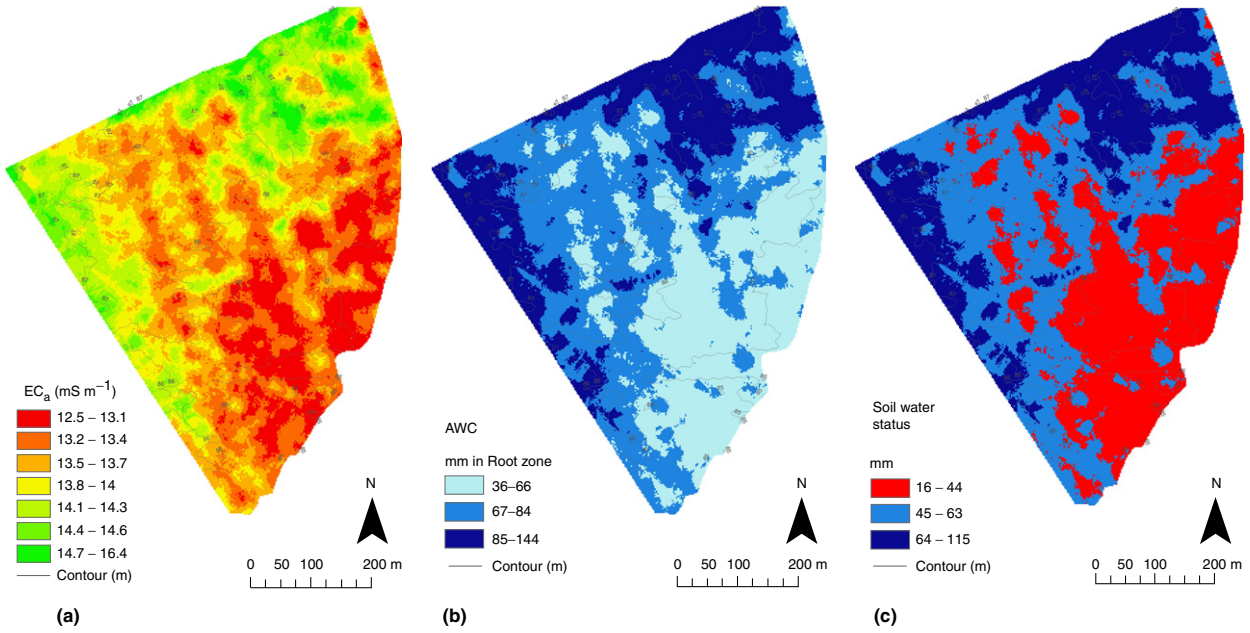

Figure 12 (a) Soil EC map, (b) available water-holding capacity map, and (c) derived soil water status map. Reproduced from Hedley, C.B., Yule, I.J., 2011. Soil water status maps for variable rate irrigation. In: Clay, D., Shanahan, J., Pierce, F. (Eds.), GIS Applications in Agriculture – Nutrient Management for Improved Energy Efficiency. Third Book in CRC GIS in Agriculture Series. Boca Raton, FL: CRC Press, pp. 173–190.

strategies to sample the full range of likely soils encountered in the area of interest. An area of 50 ha can easily be mapped in one day, by pulling the sensor behind an all-terrain vehicle, with on-board GPS, datalogger, and field computer.

Topographic features that are likely to influence irrigation efficiency (e.g., slope, aspect, and slope angle) can be derived from the DEM, and used in conjunction with EC to derive optimal sampling and monitoring positions (Minasny and McBratney, 2006).

The EM map is not only used to select soil moisture monitoring sites, but can also be used to calibrate soil EC values against soil available water-holding properties (Waine *et al.*, 2000; Godwin and Miller, 2003; Hedley and Yule, 2008; Hedley and Yule, 2009) so that a soil available water-holding capacity map can be produced, for spatial irrigation scheduling (**Figure 12**). Hezarjaribi and Sourell (2007) also used EM mapping to define zones for targeted soil sampling to assess soil AWC.

Triantafilis *et al.* (2009) describe how EM surveys employing root-zone sensing Geonics EM38 and vadose-zone sensing Geonics EM31 sensors are related to subsurface soil properties such as texture, moisture, and depth to water table; and are used to define management classes for precision management. Sherlock and McDonnell (2003) found that EM38 data could explain >70% of gravimetrically determined soil moisture variance.

Primary terrain attributes derived from the DEM, collected as part of the EM survey, or by other means, include surface derivatives such as slope, aspect, and curvature (Bishop and Minansy, 2006). Secondary terrain attributes are calculated from a combination of two or more primary terrain attributes to model spatial variation of processes across a landscape, the most commonly used being the 'topographic wetness index,' which is defined by Moore *et al.* (1991) as the natural logarithm of specific catchment area divided by the tangent of the slope, and another being the SAGA wetness index (Olaya and Conrad, 2009).

Other methods that show promise for mapping soil moisture over large areas include airborne and spaceborne remote sensing by passive microwave radiometry or active radar instruments. However, both methods are highly sensitive to surface roughness and their effectiveness is limited to flat and bare ground studies (Jonard *et al.*, 2011; Kseneman *et al.*, 2012), despite the advantage that they are not influenced by cloud cover.

Ground-based versions of these sensors (ground penetrating radar and L-band radiometer) are required for site-specific irrigation management, and these sensors are available, and have been tested on a vehicle for mapping soil moisture in a field. Differences observed between the two methods were related to different sensitivities to surface roughness, and different exploration depths; these technologies require further development before becoming commercially viable. The sensor data were calibrated against TDR-derived soil moisture measurements at each position, and 20% of the reference TDR data was required to produce a good roughness calibration model for the entire field, to correct the sensor data.

Other methods for mapping spatial heterogeneity of soil moisture include electrical resistivity tomography (Kelly *et al.*, 2011). While a strength of this method is its excellent vertical resolution, a weakness is that electrode arrays are inserted into the ground for imaging and the method cannot be mobilized. However, Kelly *et al.* (2011) used it to delineate zones of excessive water loss due to deep drainage, and this technology is therefore an advanced irrigation management technology. Kelly *et al.* (2011) used the information to position monitoring sensors to assist irrigation scheduling.

Soil moisture mapping aids advanced irrigation scheduling because this scheduling directly measures the amount of

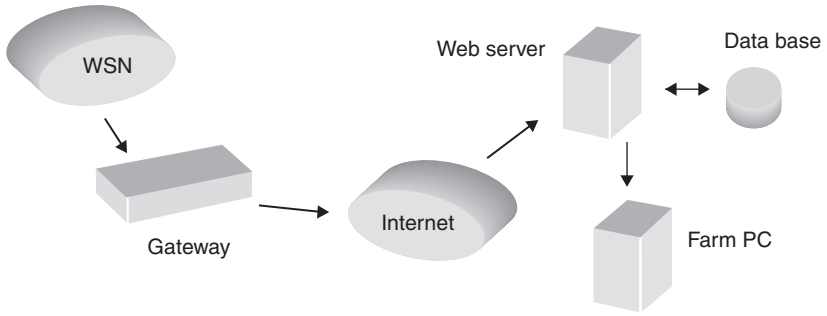

Figure 13 Schematic diagram for a wireless sensor network (WSN) suitable for irrigation control. Adapted from Ruiz-Garcia, L., Lunadei, L., Barreiro, P., Robla, J.I., 2009. A review of wireless sensor technologies and applications in agriculture and food industry: State of the art and current trends. Sensors 9, 4728–4750.

available water left in a soil profile at any one time, and the rate at which it is being used by the crop. It therefore directly monitors crop water use (Thompson *et al.*, 2007) and soil water storage under any irrigation system, and provides information in a digital form and can be used for open-loop or closed-loop decision support tools.

Recent technological advances in WSNs provide the tool for real-time high-resolution soil moisture monitoring within each management zone defined by the EM survey so that soil moisture maps can be updated on a daily basis and used either for direct control of irrigation systems or for informing land managers.

Wireless Sensor Networks

The high spatial resolution provided by GPS-enabled sensing methods (Section Advances in Irrigation Scheduling) can be further refined by smart WSN technologies, and these technologies are rapidly developing from off-line sensors using field loggers with manual downloading to wireless on-line sensor networks, within interoperable and autonomous sensor webs (see **Figure 13**). The sensor web concept is based on the SWE framework of the OGC. Within this framework, standard protocols, interfaces and web services to discover, task, exchange, and process data from different sensors and sensor networks have been defined (Thessler *et al.*, 2011). Irrigation benefits from the resulting high temporal measuring resolution with real-time data transfer from spatially optimized management zones, and spatiotemporal models can be produced to update static maps, on a daily basis, for improved irrigation scheduling (Hedley *et al.*, 2013).

These recent innovations in low-voltage sensor and wireless technologies combined with advances in internet and cellular communication technologies offer opportunities for development and application of real-time management systems for agriculture (Evans *et al.*, 2012; Pierce and Elliott, 2008; O'Shaughnessy and Evett, 2010; Coates and Delwiche, 2009).

Ruiz-Garcia *et al.* (2009) reported that wireless sensor technologies are entering a new phase as a consequence of decreasing costs, increasingly smaller sensing devices, and achievements in frequency technology and digital circuits. Nodes, each with sensors attached, wirelessly form the most efficient communication network to send data to a base station where they are stored and can be accessed remotely. Alternatively, the data are transmitted via internet or cellular means to a secure database for storage, manipulation, and informing irrigation schedules. Owing to a large number of sensors and differing accompanying protocols, a coherent infrastructure is required to treat sensors in an interoperable, platform-independent and uniform way. Standardized access to sensor observations and sensor metadata provided by the OGC compliant Sensor Observation Service (Broring *et al.*, 2011) acts as a mediator between a client and a sensor data archive or a real-time sensor system.

WSN technologies have significant potential to monitor inherent soil variability present in fields with more accuracy than existing systems. Thus, the benefit for the producers is a better decision support system that allows maximized productivity while saving water. Installation of WSNs is easier than the existing wired systems and sensors can be more densely deployed to provide local, detailed data; rather than irrigating an entire field in response to broad sensor data, each section could be activated based on local sensors.

Vellidis *et al.* (2008) developed a prototype of smart sensor array for scheduling irrigation in cotton. The system integrates moisture sensors, thermocouples, and radio frequency identification (RFID) tags. Qian *et al.* (2007) designed a new groundwater-monitoring instrument based on WSN that monitors groundwater table and temperature through a sensor. An embedded single chip processes the monitoring data and a GSM data module transfers the data wirelessly. Bogena *et al.* (2007) evaluated a low-cost soil water content sensor in a wireless network application, and Kim *et al.* (2009) developed an in-field WSN for implementing site-specific irrigation control in a linear move irrigation system. Communication signals from the sensor network and irrigation controller to the base station were successfully interfaced using low-cost bluetooth wireless radio communication. Hedley *et al.* (2013) used a wireless soil moisture sensor network optimally positioned into EM-defined management zones to inform a precision irrigation scheduling tool (**Figure 14**). The WSN monitored soil moisture and depth to water table, the latter providing a means of calculating the contribution of a high water table for subirrigating the crop.

Underground systems for monitoring soil conditions, such as water and mineral content, to provide data for appropriate irrigation and fertilization are emerging (Akyildiz and Stuntebeck, 2006) and these systems can also be used for monitoring the

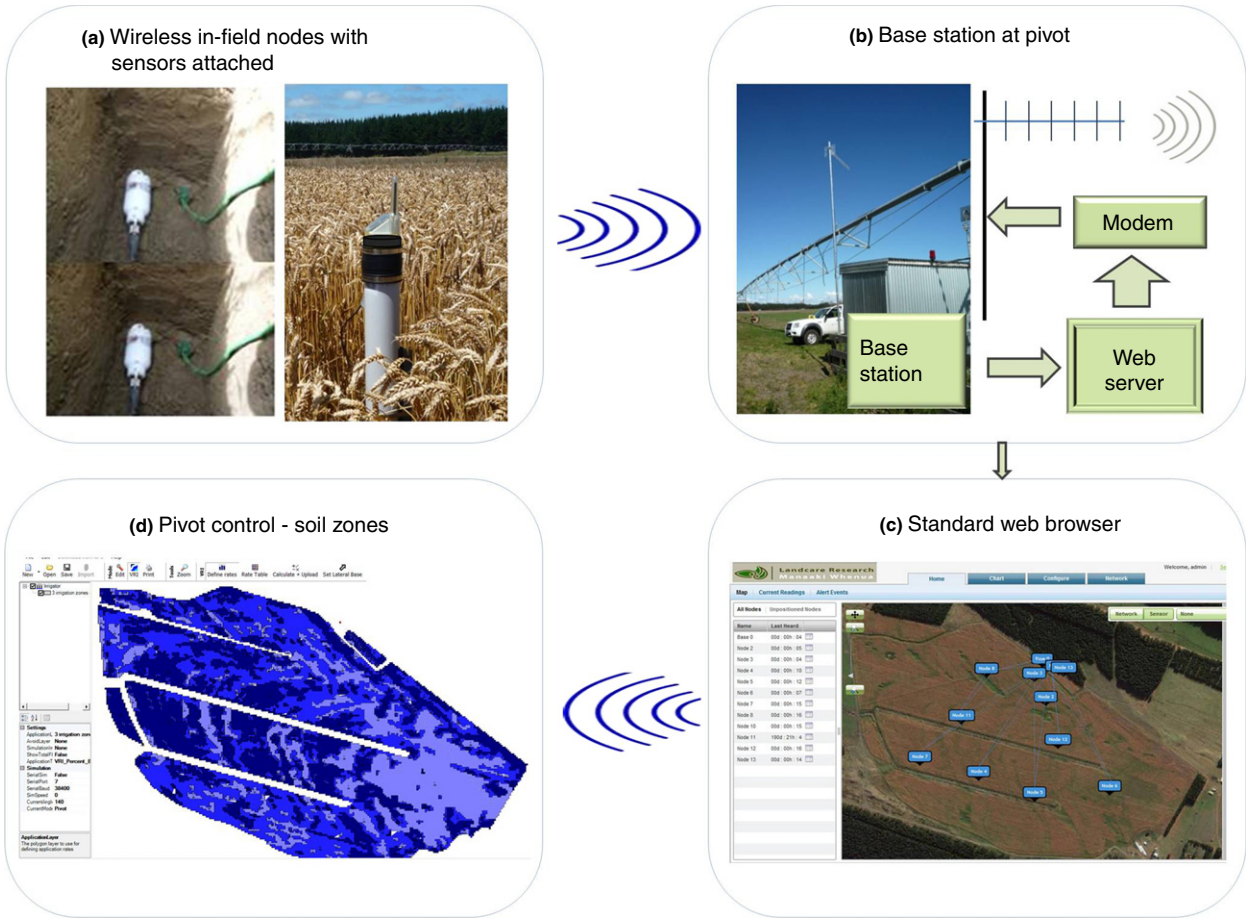

Figure 14 Flowchart to show WSN for precision irrigation scheduling. Reproduced from Hedley, C.B., Roudier, P., Yule, I.J., Ekanayake, J., Bradbury, S., 2013. Soil water status and water table modelling using electromagnetic surveys for precision irrigation scheduling. Geoderma 199, 22–29.

presence and concentration of various toxic substances in soils near rivers and aquifers, where chemical runoff could contaminate drinking water supplies. Another application can be landslide prediction by monitoring soil movement.

Further recent WSN technological advances for irrigation scheduling include

- energy-efficiency gains using adaptive decentralized reclustering protocols for node communications (Bajaber and Awan, 2011; Nesa Sudha *et al.*, 2011);
- algorithm development for handling orphaned nodes for optimal restoration into the network (Maheswararajah *et al.*, 2011);
- inclusion of wireless lysimeters for real-time online soil drainage monitoring (Kim *et al.*, 2011); and
- incorporation of bluetooth and RFID technologies for automated data capture and identification applications (Kim *et al.*, 2009; Ruiz-Garcia *et al.*, 2009).

Precision Irrigation Management

Available water supplies for irrigation are becoming increasingly limited globally and this will force major changes to the design and management of water delivery for on-farm irrigation management, as discussed elsewhere in the article (Section Simulation). Section Simulation discusses a technology that will potentially play an important role in future irrigation management of limited water supplies: site-specific variable-rate sprinkler irrigation or 'precision irrigation' modification of self-propelled center-pivot and linear-move systems (Hedley and Yule, 2009; Evans and King, 2012) (see **Figure 15**). These systems are particularly suited to site-specific management approaches because of their current level of automation and large area coverage with a single lateral pipe. Where sprinklers are modified for site-specific control, new opportunities arise to conserve water, reduce plant stress at localized positions, and reduce nutrient leaching and drainage.

Trials in New Zealand have shown that water savings are typically between 10% and 25% where variable soils occur under one system, and further savings are made by excluding irrigation from tracks, waterways, yards, sheds, and other unproductive areas (Hedley and Yule, 2011).

Management systems being developed alongside these precision irrigation systems include EM mapping to derive management zones with real-time soil moisture monitoring within each zone. The Valley VRI system uses CropMetrics, a system that derives EM and landscape change layer to identify

water-holding capacity variability across the field. These data layers are delivered through a 'Virtual Agronomist,' where the degree of field variability is used to decide on irrigation management strategies. The amount of variability relates to the amount of opportunity present, that is, the higher the variability the greater the opportunity for variable rate to benefit. Varying application rates increase input efficiency and improve yield production.

Findings from a modeling study by Hedley and Yule (2009) at five case-study sites in New Zealand found that where soil available water-holding capacity varied by 50 mm under one irrigation system then the potential water savings were approximately 10%, and variation by >100 mm gave a potential water saving of $\geq 15\%$. Savings are potentially greater in humid temperate regions (where some rainfall occurs during the irrigation season) in comparison with arid regions, where the main benefit of VRI for variable soils is a staggered start to irrigation at the beginning of the irrigation season, plus different watering strategies for soils of contrasting textural and drainage properties. Research has also been conducted to introduce wireless soil moisture sensor networks into EM and landscape-derived management zones for provision of real-time digital soil moisture information to the VRI controller. VRI control is established on-site or remotely through a software package with internet or cellular connection.

Figure 15 Variable rate irrigator, with sprinklers switched off as the irrigator crosses a farm track, saves water and reduces lameness risk in dairy cows. Photo: C.B. Hedley.

Smart phone applications are being derived for irrigation control and management, which is often more suited to operational farmer use, than a computer sitting back in the farm office. The WaterBee system has been developed in Europe independently from a VRI system, and is the result of a project undertaken by a team of 10 partners from eight European countries targeting a sustainable solution to contribute to reducing freshwater use by the agricultural sector. WSNs send readings to a soil-moisture model that automatically adapts irrigation requirements to different irrigation installations, and it is suggested that this WaterBee system will achieve real water savings while enhancing crop quality.

The importance of scale in precision irrigation

One of the most important areas that may be ignored or oversimplified in precision irrigation is in choosing an appropriate scale at which variable rate (or other) technologies should be implemented. It is quite feasible to map spatial soil variabilities and crop canopy differences at high resolution, and to engineer an application system to apply water variably. However, it is much more difficult to explain scientifically the reasons for underlying heterogeneity in crop growth and link this with confidence to decisions on variable water application. Deciding on the appropriate scale for applying water needs to be informed by a thorough understanding of the consequences of soil and crop variability on yield. Advances in precision agriculture thus need to be integrated with equivalent knowledge in precision irrigation to identify the appropriate scale(s) for system implementation. Although it may be technically and practically possible to apply water variably, it may not be economically beneficial or agronomically sensible (see Table 1).

Other Advanced Irrigation Developments

Section Overview

This section provides an introduction to a selection of other advanced irrigation technologies including the modernization

Table 1 Spatial scales of common irrigation systems

System	*Spatial unit*	*Order of magnitude of spatial scale (m^2)*
Surface – furrow	Single furrow	1000
Surface – furrow	Set of furrows	50 000
Surface – bay	Bay	10 000–50 000
Sprinkler – solid set	Wetted area of single sprinkler	100
Center pivot, lateral move	Wetted area of single sprinkler	100
LEPA[a] – bubbler	Furrow dyke	1
Traveling irrigator	Wetted area of single sprinkler	5000
Drip	Wetted area of an emitter	1–10
Microspray	Wetted area of a single spray	20

[a]Abbreviation: LEPA, low-energy precision application.

of irrigation district networks and the use of smart meters to improve the monitoring of water usage at the farm and field levels. Selected on-farm irrigation technologies to improve crop water productivity using partial root zone drying (PRD) and deficit irrigation strategies, vision sensing of crop responses for irrigation management, and the application of fertigation and chemigation are also discussed.

This section covers the following aspects:

- modernization of irrigation district networks,
- smart water metering,
- PRD and RDI,
- applied machine vision of plants for irrigation management, and
- fertigation and chemigation.

Modernization of Irrigation District Networks

The modernization of irrigation districts often involves converting the water distribution network from intermittent to 'on-demand' water supply for farmers. On-demand irrigation schemes supply water to the farm via either gravity-fed channels or pressurized pipe networks. The conveyance efficiency of pressurized pipe networks are normally significantly greater (of order 30%) than for channel systems. Pressurized water at the farm gate also provides farmers with an incentive to convert existing on-farm surface irrigation systems to potentially more efficient sprinkler or microirrigation systems.

The change from intermittent to on-demand water supply has implications not only for water use efficiency but also for irrigated crop productivity and energy usage. For example, although modernization of irrigation districts in Southern Spain has reduced the amount of water diverted to farms for irrigation, consumptive water use has increased, mainly due to a change in crop rotation (Rodriguez-Diaz *et al.*, 2011). However, in this area, the costs for system operation and maintenance have increased dramatically ($\sim$400%), primarily due to increasing energy consumption for pumping (Rodriguez-Diaz *et al.*, 2011).

In Southern Australia, Jackson *et al.* (2010) found that conversion to pressurized irrigation methods reduced energy consumption in regions where groundwater is used, the result of an increase in efficiency of water use. They also suggested that conversion of on-demand gravity-fed systems into pressurized networks is generally not appropriate where surface water supply is available. In these cases, regional investments should focus on improving the volumetric efficiency of the channel network and avoid increased energy requirements (Jackson *et al.*, 2010). However, in the Harvey Irrigation district in Western Australia (Harvey Water, 2012), the availability of elevated surface water dams close to lower elevation farms has provided the opportunity to convert a channel distribution system into a pressurized piped network that does not require pumping. Here, increased volumetric distribution efficiencies have provided water for alternative uses, whereas the delivery of low-cost pressurized water on farm has enabled the conversion of irrigation application systems and the establishment of higher value horticultural crops.

The service performance of water supply schemes is a function of the scheme and component capacities as well as the irrigation demand. Perez-Urrestarazu *et al.* (2009) observed that on-demand systems should be designed to deliver water with flow rates and pressures required by on-farm irrigation systems, taking into account the time, duration, and frequency as defined by the farmers. However, due to the probabilistic nature of users irrigating simultaneously (Anwar *et al.*, 2006) these systems are often designed with excessive distribution capacity, making them more expensive than intermittent systems (Planells-Alandi *et al.*, 2001). Similarly, pump-pressurized, on-demand systems are commonly designed and operated to supply the target pressure in each component of the pipe network irrespective of the water supplied. Sectoring, where farmers are organized to use water in turns, has been shown (Carrillo Cobo *et al.*, 2011) to be one of the most effective methods of reducing energy consumption in pressurized, on-demand irrigation networks. Computational tools involving integrated geographic information systems, real-time monitoring, and modeling of hydraulic data with decision support systems are also being used (e.g., Perez-Urrestarazu *et al.*, 2012) to improve the operational performance of pressured irrigation networks.

An alternative approach has been taken in the modernization of the open-channel delivery systems in Southern Australia. Here the decision was made to retain the open earthen channels and to seek the efficiency gains through automation along with rationalization of the network involving retirement of some smaller channels and some limited gravity pipelining and channel lining to reduce seepage losses. The classical ideas from system identification and control are used to automate the channels to provide a near on-demand system (Mareels *et al.*, 2003, 2005; Cantoni *et al.*, 2007). This system has been implemented under the name of Total Channel Control® and has resulted in distribution efficiencies in excess of 90% compared with the efficiencies of 70–75% typically achieved under manual control (see **Figure 16**).

Smart Water Metering

Knowing the amount of water being used and where it is used are important elements associated with practicing efficient irrigation. Typical pressurized irrigation farms are characterized by complex hydraulics due to numerous pipe fixtures and modifications that occur over time, and variable irrigation block flow delivery due to poor design and setup. Where flow monitoring occurs, it is often conducted by manual readings of a water meter at irregular intervals.

Smart irrigation metering involves the assessment of unique hydraulic characteristics at the source of a delivery system with multiple outlets (Pezzaniti, 2009). This requires an ability to record and automate analysis of high-frequency flow and pressure sensor data and allows not only for the continuous monitoring of water consumption but also for the identification of individual irrigation valve operation. Smart water meters have the following attributes (Giurco *et al.*, 2008): real-time monitoring, high-resolution interval metering ($\geq$10 s), automated data transfer (e.g., drive by, GPRS, and 3G), and access to data via the internet or SMS. Most modern mechanical and electronic water meters and pressure sensors have features (e.g., pulse output) that allow flow to be monitored or logged. Hence, the implementation of smart water meters for monitoring on-farm irrigation typically

(a) (b)

Figure 16 Modernization of open-channel delivery in Australia provides a near on-demand system. Photos: Michael Kai courtesy Rubicon Water.

involves the addition of a datalogger and communications to a traditional water meter and pressure sensor.

Coupling the identification of valve operation with the measured meter flows makes it possible to disaggregate the water flow so that any component within an irrigation system can be identified. This enables the flow and total volume applied to each irrigation block within the system to be recorded, providing comparative data for both the assessment of irrigation efficiency and the identification of maintenance and operating issues (e.g., pump wear, filter blockages, pipeline leaks, and emitter variations). The water use information obtained may be used to improve irrigation design and practice. Similarly, the subsequent analysis of smart water meter data can be automated and integrated with controllers to optimize water, energy, and maintenance requirements.

Partial Root Zone Drying and Regulated Deficit Irrigation

PRD and RDI strategies involve manipulating the placement of irrigation water and moisture deficit within the root zone to increase crop water use efficiency. The major differences between PRD and RDI are associated with the nature of the localized soil moisture and plant water status conditions (Ruiz-Sanchez *et al.*, 2010). Both hydraulic and biochemical signals are involved in regulating stomatal and plant growth rates in response to changes in the abiotic environment (Chalmers *et al.*, 1981; Davies and Zhang, 1991). PRD involves creating alternate drying and wetting of subsections of the plant root zone (**Figure 17**) to elevate biochemical signaling while maintaining plant water status (Loveys *et al.*, 2000; Stoll *et al.*, 2000; Dodd *et al.*, 2006). Hence, PRD strategies maintain plant water status and create a favorable physiological response through elevated biochemical signaling. RDI involves reducing the moisture availability throughout the entire plant root zone resulting in a reduced plant water status (Kriedemann and Goodwin, 2003). RDI improves crop WUE by maintaining plant water status within the prescribed limits of deficit with respect to maximum water potential (Kriedemann and Goodwin, 2003).

PRD strategies attempt to maintain water availability and plant water status simultaneously while elevating the biochemical signaling (increasing ABA levels and alkalization of sap pH) within the plant. The elevated ABA has been found (Loveys *et al.*, 2000; Stoll *et al.*, 2000) to coincide with a partial reduction in stomatal conductance and a differential effect on vegetative and reproductive production (Davies *et al.*, 2000), both of which lead to an improvement in crop water use efficiency for fruiting crops.

Practical limitations in the successful application of PRD and RDI are related to the soil hydraulic properties, volume, and frequency of irrigation water applications, and the occurrence of in-season rainfall. PRD and RDI strategies are difficult to apply in furrow irrigation systems and PRD is also difficult to implement under sprinkler irrigation systems. However, both PRD and RDI may be implemented using drip irrigation and precision applicators on large mobile irrigation machines. White and Raine (2009) suggested that the creation of a soil moisture gradient across the plant root zone large enough to trigger a PRD response is most likely to be achieved

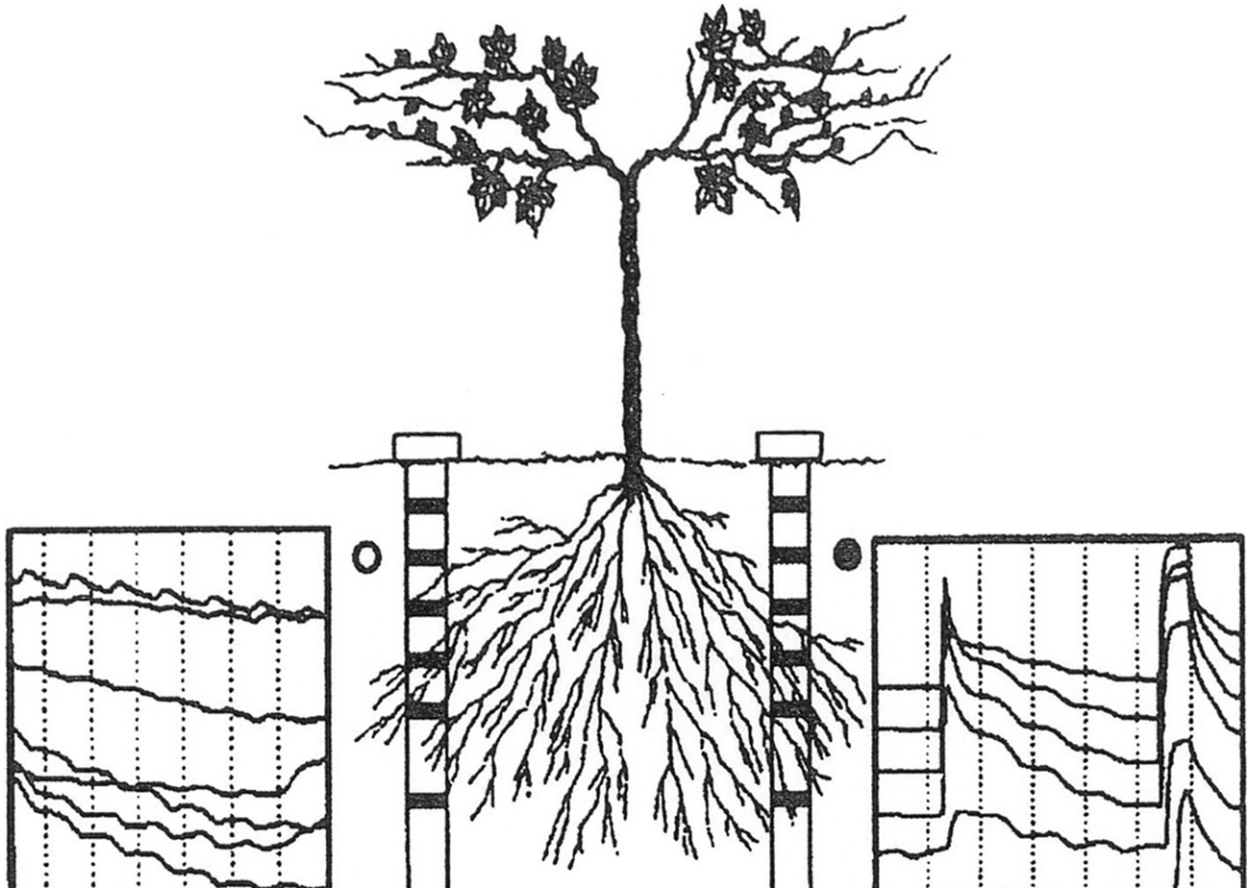

Figure 17 PRD in grapevines. Subsurface drip lines supply water to one side or the other of the vine. In this diagram water is supplied through two irrigation cycles to the right hand line. The water content of the soil at various depths is shown as output from Enviroscan sensors. Although the soil around the right hand sensor wets and dries in response to the irrigation, the soil on the left hand side of the vine continues to dry. Reproduced from Loveys, B.R., Grant, W.J.R., Dry, P.R., McCarthy, M.G., 1997. Progress in the development of partial root-zone drying. Australian Grapegrower and Winemaker 403, 18–20.

on light-textured soils located in semiarid regions that experience minimal in-season rainfall events.

RDI is particularly useful in controlling vegetative growth and increasing fruiting in indeterminate crops (e.g., cotton). For example, White (2006) found RDI (79% of predicted ET) of cotton under field conditions produced a 31.5% improvement in crop water use productivity over commercial practice (i.e., applying 100% of predicted ET). However, the largest benefits derived from deficit irrigation were associated with the management of crop agronomy (i.e., vegetative growth, fruit retention rate, and crop earliness) and the increased utilization of in-season rainfall.

Applied Machine Vision of Plants for Irrigation Management

The automated visual assessment of plant condition, specifically foliage wilting, reflectance, and growth parameters, using machine vision has potential use as input for real-time VRI and fertigation systems in precision agriculture. Crop-sensing tasks that have been successfully demonstrated using machine vision in outdoor conditions include automated identification of weed species (Slaughter *et al.*, 2008), nitrogen status (Noh *et al.*, 2005), plant size (Shrestha and Steward, 2005), and multispectral properties using narrow band imaging (e.g., Carter and Miller, 1994). McCarthy *et al.* (2010) have reviewed the use of applied machine vision for plant sensing in irrigation applications.

Farm managers typically include visual assessment of crop condition to inform management decisions (e.g., irrigation timing) and treat the whole field uniformly based on their manual observations. For example, internode length measurement (i.e., the distance between branch junctions, **Figure 18**) is part of a plant-based water stress monitoring regime for cotton suggested for growers (Milroy *et al.*, 2002). A machine vision system with access to a large proportion of the field potentially enables automatic condition assessment for different plants at high spatial frequency in the field. Such sensing capability, in conjunction with the implementation of appropriate variable-rate application hardware, enables agricultural fields to be treated as a conglomerate of control units for operations such as irrigation and fertigation (e.g., Smith *et al.*, 2009).

The design of a vision system for the measurement of plant attributes is affected by many factors, including the scale of the plant measurement (i.e., leaf- or canopy-level) and the measurement environment (e.g., a laboratory or in the field).

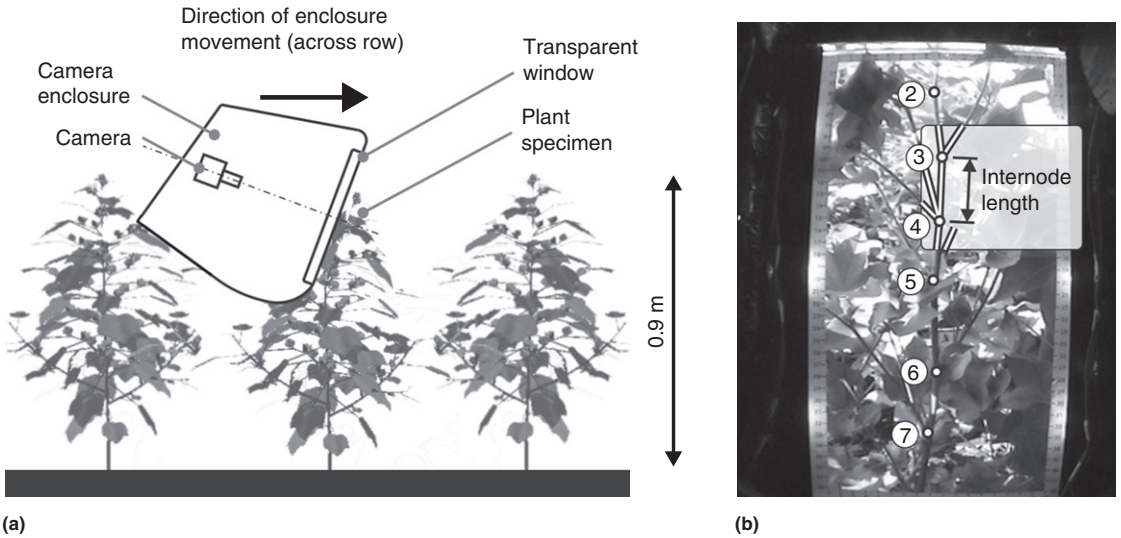

Figure 18 (a) Moving image capture apparatus; and (b) stylized sample image from apparatus, with main stem nodes numbered. Reproduced from McCarthy, C.L., Hancock, N.H., Raine, S.R., 2009. Automated internode length measurement of cotton plants under field conditions. Transactions of the ASABE 52 (6), 2093–2103; Cotton plant graphic adapted from University of Hamburg, 1998. Virtual Plants. Available at: http://www.biologie.uni-hamburg.de/b-online/virtualplants/ipivp.html (accessed 19.10.12).

Automated machine vision sensing of individual plants in the field is presently limited to early stage crops (where neighboring plants are too small to touch or overlap), or, for more mature canopies, to whole-plant characteristics such as plant biomass. The use of near-infrared (NIR) imaging, background boards, and shade structures with artificial illumination reduces the complexity of the segmentation process but adds extra components and potentially physical bulk to the overall measurement system. In the indoor environment, a monocular vision system can identify small canopy changes for irrigation scheduling purposes.

Identification of plant structure using stereo vision enjoys greater success for smaller plants. Applications in the outdoor environment typically provide overall canopy geometry, which is useful for monitoring crop growth in areas of a field or identifying plant height changes, for example, between different species (i.e., weed and crop). Determination of leaf and branching structure of individual plants is currently limited, even in indoor environments, and relies on the image having a plain background. Knowledge of plant growth patterns (e.g., phyllotaxis) potentially assists measurement by image analysis.

The sensing and image analysis task may be simplified by imaging only in that part of the electromagnetic spectrum that accentuates features of interest more effectively than the broad visible bands provided by standard RGB cameras. Sensing of different regions of the electromagnetic spectrum potentially enables discrimination of plant materials based on color (visible), cellular structure (NIR), thermal (mid-infrared), or hardness (X-ray) properties.

Machine vision systems for field use must be designed to be robust to sunlight variations (Slaughter *et al.*, 2008). Active sensing systems are less susceptible to ambient sunlight than passive sensing systems. However, low-cost (passive sensor) cameras with simple imposed illumination may also have reduced dependency on sunlight (e.g., Edan *et al.*, 2000).

Attaching a machine vision system to the gantry of a center pivot or lateral move irrigation machine potentially enables crop condition to be measured in real-time as the irrigation machine moves across the field (e.g., Colaizzi *et al.*, 2003; McCarthy *et al.*, 2009). Alternatively, tractor-mounting of the system may be desirable, so assessments can be made as the tractor moves alongside the field. On-the-go in-field sensing of geometric crop plant parameters is currently limited to leaf shape identification and biomass estimation in the foliage of small plants, or plant height and biomass estimation in fully developed canopies. To measure plant leaf-level attributes (e.g., internode length and leaf shape) in maturing field plants requires the design of a robust outdoor machine vision system that achieves a detailed structure sensing. These systems have so far only been reported for automated laboratory or greenhouse systems on a limited number of crops under controlled lighting and environmental conditions.

Fertigation and chemigation

Efficient nutrient and chemical use in agriculture involves accurate spatial and temporal placement of the applied fertilizer or chemical. Fertigation involves supplying dissolved fertilizer to crops through an irrigation system (Bar-Yosef, 1999). Although fertigation has the advantage of being able to accurately apply fertilizer, liquid application of ammoniacal fertilizers can lead to deleterious drops in soil pH (Stork *et al.*, 2003), because roots release hydrogen ions to take up ammonium ions, and this should be considered when fertigating with these compounds. Fertigation is commonly applied using both surface and pressurized irrigation application systems. When combined with an efficient irrigation system, both nutrients and water can be manipulated and managed to maximize marketable yield and nutrient efficiency (New South Wales Dept of Primary Industries (NSW DPI), 2000). Soluble

inorganic nutrients are normally used for fertigation but the application of humic substances via fertigation systems has also been found (Selim and Mosa, 2012) to increase root zone moisture holding capacity in sandy soils and increase crop productivity.

Chemigation in broad-acre crops is most commonly applied by large mobile irrigation machines (i.e., center pivots or linear moves). Herbicides, insecticides, and fungicides may be injected into the main irrigation water pipe for distribution through the irrigation emitters (e.g., Quad-Spray, Senninger Irrigation Inc., Clermont, FL, USA) with the water. Alternatively, chemigation may be conducted using a separate system of distribution pipework with spray heads suspended underneath the irrigation machine truss rods to enable the application of chemical either with or without irrigation water (Foley and Raine, 2001).

The efficiency of fertigation and chemigation strategies is highly dependent on the performance (i.e., uniformity) and management of the irrigation system. Fertigation uniformity in microirrigation systems is primarily a function of emitter discharge uniformity where the fertilizer is injected during the middle third or half of the total irrigation time (Hanson *et al.*, 2006). Fertilizers injected into water applied to furrow irrigation systems are similarly affected by the nonuniformity of the applied water, with efficiencies often low due to percolation losses at the head end of the field and tailwater runoff losses. Simulation models combining the overland water flow (Saint-Venant equations), solute transport (advection–dispersion), and infiltration have been developed (Perea *et al.*, 2010; Burguete *et al.*, 2009) to evaluate and optimize the application of fertilizers in furrow irrigation systems. Modifying the water inflow hydrograph to improve the uniformity of water application and reducing tailwater runoff has been found to improve both nutrient uniformity and efficiency (Moravejalahkami *et al.*, 2012). Similarly, using alternative furrow irrigation strategies has also been found (Ebrahimian *et al.*, 2012) to increase lateral water movement, reducing water and nitrate losses via runoff and deep percolation.

Decision support systems are increasingly being used (e.g., Incocci *et al.*, 2012) to identify optimal fertigation requirements based on crop growth and environmental conditions. Site-specific fertigation of zones within conventional pressurized irrigation systems may be achieved by the installation and control of separate injection facilities for each zone. However, implementation of separate systems to date has been limited because of the expense and control complexity (Coates *et al.*, 2012). Where a centralized injection facility is used, the selection of the optimum injection strategy will be a function of the crop needs, scheduling limitations, and system design parameters including emitter type, fluid distribution system travel time, and field slope (Coates *et al.*, 2012).

Future Directions – Emerging Risks, Technical Challenges, and Future Developments

Section Overview

Despite concerns regarding international food security, and the drive to support sustainable intensification, agriculture still faces a number of challenges that are likely to hamper any widespread uptake of advanced technologies, including precision irrigation. This section identifies the emerging risks and 'drivers for change,' highlights the environmental and technical challenges constraining innovation in precision irrigation, and briefly considers selected novel technologies on the horizon that will support the future sustainability of irrigated agriculture and horticulture.

Emerging Risks

In most countries, agriculture provides significant societal benefits, by making important contributions to national economies and underpinning rural employment. Although the most obvious contribution is probably in the production of 'food' and 'nonfood' crops, agricultural ecosystems also provide other services, including regulation of air quality, climate, and water purification. Agricultural land delivers nonmaterial cultural benefits such as land for recreation and valued characteristic landscapes, supporting habitats, wildlife, biodiversity, and ecosystem services. The importance of agricultural land, including irrigated croplands, therefore goes far beyond food production – the future actions of farmers can thus have positive or negative effects on these services, all of which are likely to be affected by climate change.

Climate impacts on irrigated production

Internationally, agriculture is regarded as one of the sectors at most risk from a changing climate, due to the impact of increased temperatures, reduced rainfall, and increased frequency of extreme events, not only in the tropics but also in humid and temperate environments (Falloon and Betts, 2010; Knox *et al.*, 2012). Outdoor rainfed and irrigated crops are particularly sensitive, both directly from changes in rainfall and temperature and also indirectly, as any change in climate will also impact on the agricultural potential of soils by modifying soil water balances and changing land suitability for production (Daccache *et al.*, 2012). These changes will in turn affect the availability of water to plants and impact on other land management practices (e.g., trafficability for seedbed preparation, spraying, and harvesting) including the demand for irrigation (Daccache *et al.*, 2011). In regions where rainfed agriculture is dominant, changes in the timing, distribution, and reliability of rainfall may force a gradual switch to irrigated production, to maintain crop yields. Here precision irrigation could become important, particularly for supplemental irrigation. By combining better weather forecasting techniques to make better use of effective rainfall with, for example, VRI, the negative impacts of agroclimate uncertainty on crop yield and quality could be reduced.

Farmers also face a range of 'nonclimate' risks that potentially represent a more immediate threat to sustainable food production than climate change. Most notable is the increasing burden of environmental protection and its consequent impacts on water resources (both supply and allocation) for irrigated agriculture (Knox *et al.*, 2010). However, investment in advanced precision irrigation technologies still requires consistent and reliable supplies of water.

Demands for greater environmental protection

Governments and society are seeking greater levels of environmental protection. In irrigated agriculture, probably the greatest short-term risks relate to the impacts of new water regulation. For example, in Europe, a number of new directives have recently been enforced, including the Water Framework Directive (WFD 2000/60/E). Despite its title, the WFD is as much about land management as it is about water management. It is the most substantial legislation produced by the European Commission and provides the major driver for sustainable management of water across Europe. By 2015, it requires that all inland and coastal waters within defined river basins reach at least 'good status' and defines how this should be achieved through the establishment of environmental objectives and ecological targets for surface waters. The WFD applies to all waters to tackle diffuse source pollution, ranging from fertilizer and pesticide applications on rainfed and irrigated land to urban runoff. In agriculture, the dependence on fertilizers and pesticides means that many farms may be subjected to much greater levels of surveillance to ensure that diffuse pollution from cropped areas is not contributing to water quality degradation. Irrigated agriculture is widely viewed as a key target for improvement. Similar pressures on irrigated farming are known to exist in other continents including the US and Australasia.

However, the rising costs for fertilizer (and energy for water pumping) are themselves acting as an industry brake, with many irrigated farms actively seeking new measures to reduce fertilizer inputs and water use. Collectively, these may provide a positive indirect response to water regulation and drive the uptake of precision irrigation technologies. These could help reduce nitrate leaching risks, nonbeneficial losses of water off-farm, and levels of energy consumption (and hence carbon footprint) for irrigated production.

Although most environmental regulations are implemented at the river basin or catchment scale, their impact will be felt at the farm level, particularly when irrigated farms are located in water-stressed catchments or in proximity to internationally protected habitats or environmentally designated sites. Under these conditions, precision agriculture practices, including irrigation, could again help reduce some of the impacts of agricultural water abstraction on local habitats and the risks associated with nitrate leaching to the environment.

Finally, farms in the future may be subjected to increasing levels of monitoring and scrutiny (traceability) to demonstrate compliance with national and international regulation. Precision irrigation technologies will undoubtedly have an increasing role in demonstrating 'best practice' in irrigation management. In this context, technologies that target water applications both spatially and temporally, taking into account heterogeneities in soil moisture, crop development, and climate, are likely to be viewed positively by environmental regulators. In parallel, changes in water regulation are exposing irrigated farms to new water supply risks.

Competition for water resources

Internationally, irrigated agriculture faces rising competition for access to reliable, low-cost, and high-quality water. In Northern Europe, for example, farmers are under increasing regulatory pressure to improve irrigation efficiency; indeed, demonstrating 'efficient' water use is a prerequisite for renewing an abstraction license (permit) (Knox *et al.*, 2012). In Mediterranean Europe, where irrigated agriculture accounts for approximately 60% of all abstractions (OECD, 2012), production is at risk due to increasing water scarcity and competition for scarce resources (Wriedt *et al.*, 2009). In some countries, abstraction regimes are in place, but in others new frameworks for regulation, including those for irrigation control are being implemented. Within these frameworks, higher levels of water efficiency will inevitably be required. Precision irrigation, often only considered in the form of drip (or trickle) irrigation, is often seen by water regulators as being 'good' for the environment. Other forms of precision and VRI will no doubt be encouraged.

Figure 19 Overhead irrigation on iceberg lettuces using a modified mobile hosereel fitted with a boom. Before harvest, the sprinklers are replaced with drop tubes to avoid soil splash impacting on crop quality. Photo: J. Knox.

In many catchments where irrigated agriculture is concentrated, rising demand for water between different sectors (notably, agriculture, public/domestic supply, and industry) coupled with reduced allocations to meet environmental flows means that allocations for irrigation are becoming less reliable and more expensive. The situation is exacerbated by examples where irrigated agriculture is cited as being the primary cause of environmental damage and overabstraction, mainly during the summer months when river and groundwater levels are at their lowest and irrigation demands peak.

In future, farmers will need to demonstrate more efficient and sustainable use of water to secure rights (licenses/permits) for irrigation abstraction. Technical measures such as switching from sprinkler to micro (drip)-irrigation are often promoted by industry and the regulator to reduce the environmental impact of abstractions and increase water efficiency. Replacement of overhead irrigation sprinklers with drop tubes is an example of system modification to efficiently deliver irrigation to the root zone of a salad crop, also minimizing soil splash onto the plant, to reduce the amount of washing required during the processing stage (Figure 19). However, any environmental gain may be limited if more efficient techniques such a precision irrigation do not result in a reduction in net water use, but simply support an increase in irrigation command. Any water 'saved' via precision irrigation could be reallocated to other crops; the

environmental impact could thus be negative not positive, due to reduced return flows from previously 'inefficient' irrigation (Hedley and Yule, 2008; Perry *et al.*, 2009).

Drivers for Change

Development of innovative approaches to combine better spatial and temporal knowledge of soil, crop, and equipment management practices to reduce variability in crop yield and quality through advanced irrigation technologies is a major 'driver for change,' whether driven by consumer (market), regulatory, and public demands for greater environmental sustainability.

To maintain output, agriculture has intensified and become much more specialized, and for many farmers, investment in irrigation has provided the basis to maintain or increase profitability. For example, in high-value cropping, irrigation is not a marginal activity used to boost yield, but an essential component of production to deliver premium quality, continuous supplies of produce to processors and retailers. It has also become a prerequisite for meeting the increasing market demands for quality and continuity of supply. Despite this external driver, irrigation of field crops in many parts of Europe and elsewhere has changed relatively little over the last few decades. However, with rapidly rising labor and energy costs, farm businesses are now assessing the impacts of irrigation variability (nonuniformity) on crop yield and quality much more proactively (see e.g., **Figures 5**, **6**, **15** and **19**). This is because the quality assurance benefits of irrigation can be substantial and relate to the whole crop, not just to the extra marginal yield due to irrigation. Quality criteria are increasingly specified as a condition of contract and sale, and failure to meet quality requirements can lead to large price discounting, and possibly rejection and loss of contract.

Over the past decade, grower or crop assurance schemes have also played an important part in driving water efficiency in irrigation and supporting uptake of advanced irrigation technologies. These schemes require growers to audit their irrigation systems and provide traceability and accountability in support of public health and environmental protection regulation. These schemes have also provided the basis for growers to comply with industry protocols for food safety and crop assurance (Monaghan and Hutchison, 2012).

In the future, water cost is likely to become a major driver for change – not necessarily the unit cost for securing access to a water supply, but more likely the energy costs associated with conveyance and pressurized delivery of in-field irrigation. With increased attention to water conservation during drought spells, competition from environmental, recreational, public/domestic use, and regulatory constraints, the current economics of VRI, which are proving a deterrent to investment, may well change (Sadler *et al.*, 2005; Hedley and Yule, 2009).

Future Developments

Combining wireless technologies with variable rate application

On most farms, making maximum use of soil moisture and rainfall, knowing precisely where and when irrigation has to be applied, and then applying it accurately and uniformly are the fundamental steps in the pathway to water efficiency (Knox *et al.*, 2012). Although irrigation is an essential component of production to maximize yield in arid and semiarid regions, there is growing evidence that optimized irrigation regimes under temperate and humid conditions can also lead to improved postharvest quality resulting in reduced crop waste through the food supply chain. However, at present most farmers are restricted in their ability to match the timing and frequency of irrigation applications to inherent spatial and temporal variations in soil moisture and crop growth. They generally have only limited information on plant water status, rely on limited *in-situ* point measurements of soil as a proxy for field-scale soil moisture availability, and use conventional irrigation systems that lack sufficient flexibility and technology (control) for variable water application.

However, developments in crop and soil moisture sensing, coupled with wireless telecommunications for in-field soil moisture monitoring and thermal imaging, now provide opportunities to develop smarter, closed-loop systems capable of applying water variably both across and along fields. Most research to date has focused on developing such technologies for use under sprinkler (center pivot and linear move) irrigation systems. The potential for VRI using individually controlled solenoid valved sprinklers, similar to those used in the sports turf (golf) industry, is also now being evaluated in high value horticulture, where sprinkler irrigation is still the preferred method of application.

Digital advances in cloud computing and remote sensing

Alongside innovations in irrigation systems and soil moisture monitoring, digital advances using the latest cloud computing technologies are also moving swiftly into precision agriculture. Put simply, cloud computing involves using networks of remote servers hosted on the internet to store, manage, and process data, rather than hosting information and data on local servers. They generally rely on wireless data transfer and mobile web applications, in combination with other tools and spatial technologies including GPS and GIS. Cloud technology is well established within data-intensive industries, but only recently emerging in agriculture where various applications are being marketed. For example, in the USA, cloud services provide on-farm support from agribusinesses and consultants, for agrochemical application management. Other precision-related tools are now emerging.

New uses relating to precision irrigation could include applications for mobile devices operating in the cloud to spatially monitor soil moisture, crop growth, and irrigation in real-time via in-field sensor arrays. Other cloud uses include providing data to refine planting and harvest operations, by integrating GPS and GIS data or managing equipment performance (pressures, flow rates, abstractions) at district or catchment scales. RFID tags, which automatically download data, are also becoming more widespread in agriculture. For example, tagging systems have been developed to collect data on the moisture content of straw bales, weight, and in-field position (GPS); in the future, similar cheap, possibly biodegradable, microtags could be deployed across fields to measure seasonal changes in soil moisture, organic content, crop canopy development, and canopy stress, or for

monitoring and optimizing energy needs across pressurized irrigation distribution networks (Carrillo Cobo *et al.*, 2011). However, data security issues relating to confidentiality, integrity, availability, and accountability still need to be resolved before cloud technology can be fully integrated into precision irrigation.

There is also increasing potential for new applications linking the use of high-resolution and -frequency remote sensing data (e.g., MODIS) to inform on-farm irrigation management, including mapping croplands, and monitoring spatial changes in crop cover in support of farm monitoring of irrigation water use and evapotranspiration (ET) (Thenkabail *et al.*, 2012). Recent remote sensing developments provide scope for mapping croplands in a routine, rapid, and consistent way, with sufficient accuracy (Congalton and Green, 2009). There is also potential to use remote sensing to identify irrigated regions, where improvements in water productivity should be targeted to reduce 'yield gaps' (Fereres *et al.*, 2011). By integrating advanced technologies such as cloud computing with developments in precision irrigation and remote sensing, there is also broader scope to improve one's understanding of the links between food production and water scarcity, and the impacts of climate change on food supplies.

Summary

In the future, committed efforts will be needed to implement advanced irrigation technologies that are appropriate for different types of farming systems to improve both water and energy efficiency while maintaining or improving crop yield and quality. Considering the demands on natural resources, precision irrigation is likely to play an increasingly important role, but a number of factors remain important. These include the changing economics of irrigation, the rising cost of energy, the increasing importance of crop assurance, and the role of retailers (supermarkets) in influencing consumer attitudes and behavior toward quality assurance and fresh produce.

The uptake of precision irrigation is likely to be slow and dependent on appropriate support systems and knowledge transfer to engage farmer support and trust. Insufficient recognition of field variability, the lack of a whole-farm approach, limited knowledge of the links between crop quality and precision irrigation, and the alignment of crop assurance schemes with environmental auditing will all need to be resolved.

The way forward for precision irrigation seems to mirror observations from precision agriculture. Here the key has been to keep the farmer's perspective central to the objective. Farmer needs, of course, vary depending on the agricultural system (e.g., intensive horticulture vs. extensive broad-acre cropping), the scale of business (e.g., family farm vs. agribusiness), underlying agroclimatic conditions (e.g., arid vs. humid), and many other socioeconomic factors (e.g., attitudes to risk, etc.). The tacit knowledge of farmers is thus critical.

New farm-scale precision equipment assists farmers to fine-tune the existing management procedures, but requires the accompanying decision support tools to monitor and adapt this new level of control.

Such technologies can be carefully positioned to fill specific (and crucial) gaps in the existing irrigation toolkits using the tacit knowledge of farmers (McBratney *et al.*, 2005) to assist improved farm-scale irrigation practice.

The limited opportunity to increase global freshwater allocations for irrigation (OECD, 2012) will require collective initiatives beyond the farm gate to optimize regional-level tradeoffs. These include tradeoffs between improved water use efficiency of modern pressurized systems versus their greater energy consumption; as well as tradeoffs between the best use of irrigation to meet global food demands and the pressing need to maintain the multiple ecosystem services that global freshwater resources provide.

Glossary

Biochemical oxygen demand The amount of dissolved oxygen needed by aerobic biological organisms in a body of water to break down organic material present during 5 days of incubation at 20 °C (BOD_5).

Desalination Technological process that allows the removal of salt and other minerals from saline water to produce freshwater suitable for human consumption and agricultural or industrial use.

Drainage water The water naturally or artificially removed at surface or subsurface from an agricultural area and that contains chemicals, mainly salts leached from the soil.

Refractory organic chemicals Organic compounds, either natural or synthetic, that are resistant to being broken down through conventional treatment processes.

Sodium adsorption ratio (SAR) A measure of the sodicity of soil, hence of the suitability for use in irrigation and is determined from the ratio of the concentrations of the Na^+ ion relative to those of the Ca^{2+} and Mg^{2+} ions.

Water reclamation Treatment or processing of wastewater to make it reusable.

Water recycling The wastewater after appropriate treatment is redirected back to its original use.

Water reuse The use of treated wastewater for beneficial purposes such as agricultural use.

Water scarcity A situation when water availability in a country or in a region is below 1000 m^3 per person per year. Water scarcity refers to various regimes affecting water availability: Natural aridity and drought, and man-made water scarcity and desertification.

Introduction

Global socio demographic and environmental change poses unprecedented challenges to mankind. Drivers of global change such as climate change, population growth, urbanization, industrialization, and rising income, living standard, and energy demand will all characterize the future demand for water. Population growth and water scarcity also drive the need to the use/recycling of nonconventional water resources, mainly saline and drainage waters, treated wastewater and desalinated water for irrigation and other uses in many countries (Pereira *et al.*, 2009; Wichelns and Drechsel, 2011; Hanjra *et al.*, 2012).

The use of waters with different degrees of salinity, either drainage water or groundwater from low-quality aquifers, is a common and old practice in water-scarce regions. Differently, the reuse of wastewater or desalinated water is a relatively recent practice. All have in common the need to control the impacts on the environment, to manage crops in agreement with characteristics of the used water and, in case of wastewater, the need to avoid health consequences for workers and consumers of the produces.

Appropriately treated wastewater is a drought-proof and renewable supply of water. Wastewater irrigation can supply plant food nutrients inexpensively, mitigate water scarcity, save disposal costs, reduce pumping energy cost, and thus minimize carbon emissions. However, the negative health and environmental risks of wastewater irrigation need to be addressed, such as pathogens, excess nutrients, salts, toxic elements, and heavy metals (WHO, 2006a,b; Pereira *et al.*, 2009; Hanjra *et al.*, 2012). These negative impacts often result in negative consumer attitudes toward the use of wastewater for irrigation. Nevertheless, awareness of health risks is not high among farmers. These facts call attention to the need for developing educational and awareness programs that may make easy the adoption of best management practices and acceptability by the consumers.

A better understanding of the positive and negative environmental health impacts of wastewater use in agriculture can improve management of wastewater use and offer positive-sum solutions for human welfare and the environment. The wastewater demand for irrigation will continue to increase, especially by the millions of small farmers who depend on wastewater irrigation (Qadir *et al.*, 2010). Hence, in aiming at health safety of consumers and field workers, the challenge is to satisfy that demand with wastewater treated to the appropriate level, which justifies that particular attention is given to wastewater treatment as well as to health-related issues.

Concern about the sustainability of water use for feeding the future human population is the strong motivation to understand the potential of the use/recycling of nonconventional water resources and nutrient energy recycling in irrigated agriculture. These uses call for the development of innovative governance strategies to meet the future water demand, to enhance participation of water users in healthy and environmentally sound management of water at system and farm levels. The socioeconomic benefits from treated wastewater use in agriculture (Winpenny *et al.*, 2010) have so far not been adequately quantified and innovative approaches are required.

Seawater desalination will play an important role in addressing the challenge of global water scarcity. Nevertheless, desalinized water is very expensive and high in energy consumption, yet it is available as demineralized. This calls for mineralizing it when used for irrigation, so that fertilizers, microelements, and other elements as calcium are added to enhance the balance of nutrients for crops. Differently, using saline waters and wastewater requires careful attention to the salt components to avoid soil degradation by salinity and

plant toxicity by salts or phytotoxic elements and compounds. Attention is therefore given to the impacts on soils and the environment.

The sustainable use of nonconventional water resources needs that water uses are mostly beneficial, the water productivity is high, and the economic results are positive in terms of farming returns. To achieve that sustainable use of water, it is required that the respective pathways be known to clearly identify benefits and problems (Figure 1).

When using freshwater or low salinity water, the focus is on water conservation and saving, thus applying only the water that is required for achieving the crop yield, minimizing water wastages and losses and maximizing the water productivity and the economic return. Differently, when using wastewater the priority must be assigned to safe use of water in terms of public health (Figure 1). Maximizing the beneficial uses keeps a high priority for wastewater or saline water uses but an at least equal priority must be assigned to minimize environmental impacts due to pathogens, phytotoxic effect and excess of salts that may degrade the soil, the flora, and the fauna. This includes the preservation of water bodies that function for the disposal of the excess water and related riparian fauna and flora. Maximizing the water productivity must then be a priority constrained by the control of health and environmental impacts and by the economic farm return.

Agricultural Use of Saline Water and Recycling of Drainage Water

Characteristics and Impacts of Saline Waters

Saline water includes water commonly called brackish, saline, or hypersaline from different sources, including aquifers that are naturally saline or became saline due to human activities, and drainage effluents from agricultural land. Agricultural drainage waters are a resource for irrigation and other uses. However, drainage water may be the source for various pathogens and appropriate care is required. When treated this water may be reused for several processes (Tanji and Kielen, 2002; van der Molen *et al.*, 2007). Freshwater is considered to have a total dissolved solids (TDS) concentration of less than 500 mg l^{-1}, that is, electrical conductivity (EC) below 0.7 dS m^{-1}. Saline and brackish water will have TDS of 500–30 000 mg l^{-1}(0.7–42 dS m^{-1}), whereas seawater has TDS averaging 35 000 mg l^{-1}(49 dS m^{-1}).

Drainage water is used for irrigation in many parts of the world, mainly in CA, USA; India; Egypt; Israel; China; North Africa; and Middle East. There are abundant reports on its use (e.g., Minhas *et al.*, 2006; Rhoades *et al.*, 1992; Shahid *et al.*, 2013; Sharma and Minhas, 2005; Singh, 2009). The use of highly saline waters may be feasible for halophytes, which

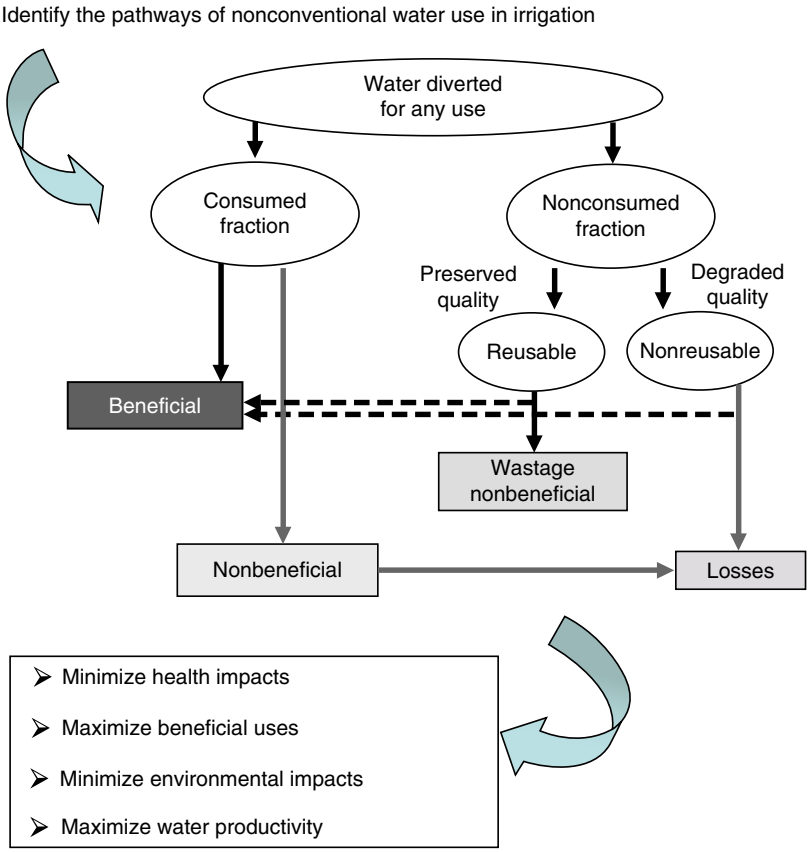

Figure 1 Efficient nonconventional water use and identification of related pathways. Adapted from Pereira, L.S., Cordery, I., Iacovides, I., 2009. Coping with Water Scarcity. Addressing the Challenges. Dordrecht: Springer, p. 382 and Pereira, L.S., Cordery, I., Iacovides, I., 2012. Improved indicators of water use performance and productivity for sustainable water conservation and saving. Agricultural Water Management 108, 39–51.

could be explored for human and animal consumption or for landscape uses (e.g., Cassaniti *et al.*, 2012; Díaz *et al.*, 2013).

The quality of drainage water for use in irrigation may be summarized as follows (van der Molen *et al.*, 2007):

- very good, <1 dS m^{-1}, appropriate for all crops;
- good, 1–2 dS m^{-1}, appropriate for most crops;
- moderate, 2–3 dS m^{-1}, appropriate for tolerant crops;
- poor, 3–6 dS m^{-1}, appropriate for tolerant crops, with appropriate leaching;
- very poor, >6 dS m^{-1}, appropriate but not recommended for irrigation. Usable to irrigate halophytes, maintain water levels in fish ponds, secure water levels in brackish coastal lakes, leaching salt-affected soils during the initial stage.

Waterlogging, salinity, and related problems have arisen in many irrigation areas where freshwater is used for irrigation. Such problems could arise even more quickly and more severely when saline water is used. The major potential hazards associated with the use of saline water in agriculture may be summarized as follows:

1. Yields decrease, which relate to:
   - reduced soil water availability to the crop due to increased soil water osmotic potential and reduced soil infiltration rates;
   - soil crusting, affecting infiltration, erosion, and crop emergence;
   - toxicity to the crop when the concentration of certain ions exceeds that of crop tolerance; and
   - imbalance of nutrients available to crops.
2. Soil degradation due to:
   - salinization when salts accumulate in the root zone if leaching and drainage are insufficient or inappropriate;
   - sodification when there is high sodium content in relation to other cations and the soil complex accumulates this excess sodium. Sodification causes soils to lose their structure, tilth, become dispersive, and these soils have reduced infiltration and permeability; and
   - loss of soil productivity in relation to salinization, sodification, imbalance of nutrients, and reduced water availability.
3. Environmental hazards from:
   - soil degradation;
   - groundwater and surface water salinization;
   - damages to the soil environment affecting plant and animal communities, and soil biodiversity;
   - desertification due to degradation of the soil, water, and environmental conditions;
   - development of aquatic weeds, algal blooms, and eutrophication in water bodies receiving nutrients and drainage effluents, particularly nitrates, thus affecting waterways and canals as well as the wildlife that inhabits ponds, lakes, and reservoirs; and
   - presence of particular ions to levels exceeding specific health and safety thresholds, which affect either plants sensitive to those ion concentrations, or animals that drink those waters, such as the selenium in drainage waters in California.
4. Public health hazards due to:
   - toxic ions such as heavy metals that, despite infrequent ingestion, are cancerous when accumulated in humans and
   - vectors of disease, such as mosquitoes and snails, which develop better in saline waters, mainly when rich in nutrients, which may affect populations living in areas using saline water or reusing drainage waters.

The use of saline water for irrigation requires:

- integrated management of water of different qualities at the levels of the farm, the irrigation system, and the basin (e.g., Rhoades *et al.*, 1992; Wallender and Tanji, 2012);
- adopting irrigation methods with high performance as discussed below;
- adopting appropriate irrigation scheduling providing for the satisfaction of crop water and using minimal leaching fractions to minimize deep percolation and runoff (Allen *et al.*, 1998, 2007);
- monitoring of soil and water quality, providing feedback that helps implement the optimal operation and control of the irrigation systems (Shahid *et al.*, 2013; Wallender and Tanji, 2012);
- promotion of tools, particularly models (Oster *et al.*, 2012), to predict long- and short-term effects of irrigation water quality on crop yields, soil properties, and quality of the environment;
- training of irrigation farmers and agricultural officers; and
- pilot areas to test and assess irrigation and soil and crop management practices for using saline water, including shallow water tables associated with deficit irrigation.

Criteria and Standards for Assessing the Suitability of Water for Irrigation

Consolidated standards have been made available in FAO publications (Ayers and Westcot, 1985; Rhoades *et al.*, 1992) and further developed in various other publications such as Tyagi and Minhas (1998) and Wallender and Tanji (2012). This has made it possible to define the main water quality parameters and management that need to be known to allow saline waters to be used safely in irrigation. Standards include:

1. Water quality characteristics to be considered for irrigation to assess the suitability of saline water concerning
   - salinity hazards (TDS and EC);
   - soil crusting and permeability hazards (sodium adsorption ratio (SAR) or adjusted SAR, EC, and pH);
   - specific ion toxicity hazard (e.g., Na^+, Cl^-, B, and Se, among others); and
   - nutrient imbalance hazard (excess NO_3^-, limited Ca^{2+}, PO_4^{3-}).
2. Parameters required to evaluate the quality of saline water on a routine basis including TDS, EC, concentration of ions (mainly Ca^{2+}, Mg^{2+}, Na^+, CO_3^{2-}, HCO_3^-, Cl^-, and SO_4^{2-}), SAR, or the adjusted SAR under certain conditions, trace elements (such as Se, As, B, Mo, Cd, Cr, and Cu), as well as other potentially toxic substances of agricultural origin.

Table 1 Water quality for irrigation and required restrictions in use

Problems	*Water quality characteristic*	*No restrictions*	*Slight to moderate restrictions*	*Severe restrictions*
Salinity effects on water availability	Electrical conductivity (dS m^{-1})	<0.7	0.7–3.0	>3.0
	Total dissolved solids (TDS) (mg l^{-1})	<450	450–2000	>2000
Salinity effects on soil infiltration	Sodium adsorption ratio (SAR) <3	EC > 0.7 dS m^{-1}	EC: 0.7–0.2 dS m^{-1}	EC < 0.2 dS m^{-1}
	3–6	>1.2	1.2–0.3	<0.3
	6–12	>1.9	1.9–0.5	<0.5
	12–20	>2.9	2.9–1.3	<1.3
	20–40	>5.0	5.0–2.9	<2.9
Toxicity	Sodium			
	Surface irrigation: SAR	<3	3–9	>9
	Sprinkle/spray (meq l^{-1})	<3	>3	
	Chloride			
	Surface irrigation (meq l^{-1})	<4	4–10	>10
	Sprinkle/spray (meq l^{-1})	<3	>3	
	Boron (mg l^{-1})	<0.7	0.7–3.0	>3.0
	Trace elements	Variable		
	Bicarbonate (meq l^{-1}) (sprinkle/spray)	<1.5	1.5–8.5	>8.5
Plant nutrition	pH	6.5–8.5		

Source: Adapted from Ayers, R.S., Westcot, D.W., 1985. Water quality for agriculture. FAO Irrigation and Drainage Paper 29 Rev. 1. Rome: FAO.

3. Water quality standards already available should be adjusted for the specific conditions of saline water use, including soils, climate, crops and crop sequences, and irrigation methods.
4. Attention must be paid to possible hazardous effects of trace elements on people or livestock that consume crops produced using water having such elements (e.g., As and Se).

The main water quality characteristics for saline waters are summarized in **Table 1**, with indications of the restrictions on their use, which mainly concern crop tolerance to salts, the need for leaching, specific requirements for the irrigation methods and systems, plus soil management practices and fertilizer practices.

Crop Irrigation Management using Saline Water

Crop responses to salinity vary with species and, to a lesser degree, with the crop variety. The tolerance of crops to salinity is generally classified into four to six groups from sensitive (or nontolerant), where most horticultural and fruit crops are included, to the tolerant, which includes barley, cotton, jojoba, sugarbeet, several grass crops, asparagus, and date palm. Full lists of crop tolerance classes are given by Hoffman and Shalhevet (2007). In addition, halophytes may be commercially explored using highly saline water (e.g., Cassaniti *et al.*, 2012).

The behavior of various crops under irrigation with water of different degrees of salinity varies with species, varieties, and the crop growth stages. As irrigation water salinity increases, germination is delayed. Germination is adversely affected for most field crops when the EC of the irrigation water, or the soil saturation extract, reaches a threshold of 2.4 dS m^{-1}. Adverse effects occur at lower values (<1 dS m^{-1}) for nontolerant crops, and at higher values for tolerant crops (generally not more than 4 dS m^{-1}). However, responses of a tolerant crop become affected when the crop is irrigated with saline water in successive years.

The germination and seedling stages are the most sensitive. Any adverse effects at such stages will lead to a reduction in crop yields proportional to the degree of plant loss during germination and establishment. At this stage, water of good quality should be used, especially if plants are sensitive. Besides germination and crop establishment, most crops are more sensitive to salinity during the reproductive phase. Other critical stages vary from crop to crop. Case studies are reported in the literature (Tyagi and Minhas, 1998; Sharma and Minhas, 2005; Wallender and Tanji, 2012).

The effects of the salinity on yields may be estimated as follows (Ayers and Westcot, 1985; Rhoades *et al.*, 1992; Allen *et al.*, 1998):

$$\frac{Y_a}{Y_m} = 1 - (EC_e - EC_{e\ threshold})\frac{b}{100} \quad [1]$$

where Y_a and Y_m are the actual and potential crops yields (kg ha^{-1}), when the crop techniques are appropriate to the local environmental conditions and no water stress affects the crop; b is a crop-specific parameter, which describes the rate of yield decrease per unit of excess salts (% per dS m^{-1}), and EC_e and $EC_{e\ threshold}$ are, respectively, the actual EC of the soil saturation extract and the crop-specific $EC_{e\ threshold}$ above which the crop is affected by salinity. The $EC_{e\ threshold}$ ranges from 1.0 dS m^{-1} for very sensitive crops, such as carrots and beans, up to more than 7.5 dS m^{-1} for barley, cotton, and tolerant grasses. The b rate of decrease in yield per unit increase in EC varies from more than 15 (% per dS m^{-1}) for the sensitive crops, down to 5 or less (% per dS m^{-1}) for tolerant crops. The parameters b and $EC_{e\ threshold}$ are tabled in Allen *et al.* (1998) and Hoffman and Shalhevet (2007) for the main crops.

The suitability of water for irrigation based on salinity, leaching and drainage requirements, and crop tolerance to salinity must be related to irrigation management. Water and crop management must be selected to minimize accumulation

of salts in the active root zone and to eliminate salt stress, especially during the critical growing stages of the plants. These include (Pereira *et al.*, 2002, 2009; Allen *et al.*, 1998):

- appropriate selection of irrigation methods;
- efficient leaching management, including volumes and frequency, and respective drainage of the salty water away from the cropped land (Section Leaching Requirements and Strategies for Controlling Impacts on Soil Salinity);
- proper irrigation scheduling, in agreement with the available irrigation system; and
- crop rotations adapted to the prevailing conditions; considerations must include irrigation water quality, soil salinity levels, chemical and physical properties of the soils, and climatic conditions.

A major factor when using saline irrigation is scheduling and frequency. Saline water requires more frequent irrigation than freshwater because salts in the water and the soil increase the osmotic potential of the soil water, which makes water uptake by the crop roots more difficult. For irrigation scheduling purposes, it is possible to consider the total available soil water smaller than that for nonsaline soils through correcting the soil water content at the wilting point (θ_{WP}, $cm^3\ cm^{-3}$):

$$\theta_{WP\ \ salt} = \theta_{WP} + b\left(\frac{EC_e - EC_{e\ \ threshold}}{10}\right)(\theta_{FC} - \theta_{WP}) \quad [2]$$

where θ_{FC} is the soil water content at field capacity ($cm^3\ cm^{-3}$), $\theta_{WP\ salt}$ is the soil water content at wilting point ($cm^3\ cm^{-3}$) for saline conditions and b, EC_e, and $EC_{e\ threshold}$ are as defined in eqn [1]. The $\theta_{WP\ salt}$ varies from a crop to another with b and $EC_{e\ threshold}$, and varies for the soil with EC_e. Equation [2] implies the reduction of the depth of water applied at each irrigation and, simultaneously, increasing the irrigation frequency. However, those depths depend on the irrigation method and the off-farm system delivering water to the fields.

The use of straw mulch to control soil evaporation also helps controlling the upward transport of salts to the root zone, particularly when irrigation and leaching are appropriate (Bezborodov *et al.*, 2010; Pang *et al.*, 2010).

The selection of the irrigation method must consider the quality of the water and the potential for both the water and the irrigation method to produce negative impacts. A summary of the more relevant considerations is presented in **Table 2**. These refer to the capabilities for controlling:

- soil salinity hazards due to salt accumulation in the root zone;
- toxicity hazards caused by direct contact of the salty water with the plant leaves and fruits;
- soil infiltration and permeability hazards caused by the modification of the soil physical properties, mainly due to the Na ion; and
- yield hazards when the irrigation system does not allow adoption of appropriate irrigation management, that is, frequency and volumes of irrigation.

Irrigation methods are described in various irrigation manuals and their adaptability for using saline and wastewater is discussed in numerous papers. Surface irrigation methods, particularly flat basins and borders, are appropriate to apply saline waters and for salt leaching. However, they are not adequate to apply small irrigation depths. When water is delivered to the farms through surface canal systems, the delivery schedules are generally of the rotation type, and are often rigid, delivering large irrigation volumes at long intervals. These systems are well adapted for leaching, but are less appropriate for irrigation of less tolerant crops that would require small and frequent applications, for example, vegetable crops. Differently, drip irrigation is appropriate for these crops because small and frequent irrigation depths are used. Drip systems require that irrigation be monitored to avoid salts returning into the wetted bulb. Cracks forming at the soil surface must be avoided. Moreover, emitters must be carefully selected, that is, not having too small orifices, and filtration must be carefully practised with filter sizes in agreement with sizes of orifice emitters, and the system must be carefully maintained and cleaned to avoid accumulation of salts within the piping, which could induce emitter clogging.

Leaching Requirements and Strategies for Controlling Impacts on Soil Salinity

The leaching requirement is usually computed from (Ayers and Westcot, 1985)

$$LR = \frac{EC_{iw}}{5EC_e - EC_{iw}} \quad [3]$$

where EC_{iw} is the electrical conductivity of the irrigation water and EC_e is the electrical conductivity of the saturated extract of the soil. The EC_e should be the average soil salinity tolerated by the crop, not that for achieving maximum yield but to provide for attaining 70–90% of the potential yield. When a leaching fraction is applied with the irrigation water, the salinity built up of the soil is reduced nonlinearly with the size of that fraction. This may be expressed as

$$EC_e = \frac{1 + LF}{LF} \times \frac{EC_{iw}}{5} \quad [4]$$

where LF, the actual leaching fraction, is used in place of the leaching requirement, LR. This equation shows that the soil salinity EC_e increases proportionally to the salinity of the irrigation water, EC_{iw}.

The salinity built up cannot be prevented by drastically increasing the leaching fraction because this would dramatically increase the percolation of water, causing the water table to rise, plus waterlogging and degradation of the ground water quality. This further contributes to water scarcity. Therefore, depending on the crop, and the salinity of the water and soil, the minimum LF is recommended. Moreover, the application of an LF is only effective when there is high uniformity of irrigation water distribution. When uniformity is low, water percolates abundantly in some areas of the field whereas other areas are insufficiently wetted. Then farmers tend to apply more water but this produces only more percolation (e.g., Pereira *et al.*, 2007). Under conditions of water scarcity, this would be a very poor use of the available water. As reported by Hanson *et al.* (2007), leaching with drip irrigation is more effective when application depths are large

Table 2 Evaluation of the irrigation methods for use with saline water

Irrigation method	*Flat basin irrigation*	*Corrugated basin irrigation*	*Border irrigation*	*Furrow irrigation*	*Sprinkler irrigation*	*Drip and subsurface drip irrigation*	*Microsprinkling and microspray*
Salt accumulation in the root zone	Not likely to occur except for the underirrigated parts of the field when uniformity of water application is very poor. Leaching fraction difficult to control in traditional systems	Salts tend to accumulate on the tops of the ridges. Leaching before seeding/planting is required for germination and crop establishment	As for basin irrigation but infiltration control is more difficult, as is the control of the leaching fraction	Salts tend to accumulate on the tops of the ridges. Leaching is required before seeding/planting	Not likely to occur when set systems are used except for the under irrigated parts of the field due to low uniformity. Instead, problems occur with equipment designed for light and frequent irrigation	Not likely to occur except for the under irrigated parts of the field due to low uniformity, including that resulting from nozzle clogging when water filtration is poor	Not likely to occur except for the underirrigated parts of the field due to low uniformity and clogging; leaching could then be more difficult
Foliar contact, avoiding toxicity	It is possible only for bottom leaves in low crops and fodder crops, and during the first stage of growth of annual crops	Unlikely because crops are grown on ridges	As for flat basins	Unlikely because crops are grown on ridges	Severe leaf damage can occur affecting yields. Damage greater with more frequent irrigation	Not likely to occur	Leaf damage can occur, affecting yields of annual crops. Less damage for tree crops
Ability to infiltrate water and refill the root zone	Adequate because large volumes of water are generally applied at each irrigation and water remains in the basin until infiltration is complete	As for flat basins, above	As water infiltrates while flowing on the soil surface, runoff losses increase when infiltration decreases	Salinity-induced infiltration problems cause very high runoff losses	Salinity-induced infiltration problems including soil crusting may cause very high runoff losses	Problems generally do not occur except when there are not enough emitters and underirrigation is practised	Problems are similar to those for set sprinklers, so runoff losses may be important
Control of crop stress and yield reduction	Adequate because toxicity is mostly avoided, salts are moved down through the root zone, infiltration is completed, and irrigation can be scheduled to avoid crop stress	As for flat basins but depending on avoiding salt stress at plant emergence and crop establishment	Crop stress is likely to occur due to reduced infiltration, so inducing relatively high yield losses	Crop stress is very likely to occur due to reduced infiltration, so inducing yield losses	Crop stress is very likely to occur due to toxicity by contact of water with the leaves and fruits, and due to reduced infiltration, thus crop stress and yield losses may occur	These systems are able to provide for crop stress and toxicity control, so yield losses are minimized	Toxicity due to direct contact with the leaves. Nonuniform irrigation may produce crop stress and runoff. Yield losses likely

enough to appropriately control the water and salts within the wetted bulbs.

Equation [4] predicts that $EC_e = 1.5\ EC_{iw}$, when the salinity of the soil and the irrigation water are in equilibrium. Lower EC_e can occur if good quality water, including rainwater, is employed for leaching. Therefore, the conjunctive use for irrigation of saline water and good quality water is advocated, and similarly for the case of using wastewater for irrigation. An updated discussion on LF practices is given by Hoffman and Shalhevet (2007) and by Letey *et al.* (2011). The latter suggest that using a smaller LF than usually recommended may be a better option.

Several strategies are usually adopted to facilitate irrigation with saline water (e.g., Rhoades *et al.*, 1992; Shahid *et al.*, 2013). The main strategies are listed below:

1. The *dual rotation*, in which sensitive crops (e.g., lettuce and alfalfa) in the rotation are irrigated with low-salinity river water, and salt-tolerant crops (e.g., cotton, sugarbeet, wheat, and barley) are irrigated with saline drainage water. For the tolerant crops, the switch to drainage water is usually made after establishment, that is, irrigations at preplanting and at the initial crop stages are made with low salinity water. Benefits from this strategy include: (1) harmful levels of soil salinity in the root zone do not occur because saline water is used only for a fraction of the time; (2) substantial alleviation of salt buildup in the soil occurs during the time when salt-sensitive crops are irrigated with freshwater; and (3) proper preplanting irrigation and careful irrigation management during germination and seedling establishment leach salts out of the seed layer and from shallow soil depths. Difficulties include the complexity of water management for farmers and system managers and the possible lack of freshwater when it is required.
2. *Blending*, where water supplies of different salinity levels are mixed in variable proportions. Irrigation water having a quality superior to that of the saline water is obtained. Blending may be more practical on large farms because the farmer may take into consideration the crops grown and the respective growth stages. Differently, with large irrigation systems supplying many small farms it would be difficult to properly satisfy the requirements of all the crops, unless a cropping pattern is imposed for all farms.
3. *Cyclic application* of saline water and freshwater. Salinity must not be above the acceptable thresholds for the crops grown. Cycles of application of freshwater should coincide with the more sensitive growth stages, particularly for planting and seedling development, and for the leaching of the upper soil layers. This strategy has more potential and flexibility than the blending strategy.

Monitoring and Evaluation

Using brackish and saline irrigation water can be successful on numerous crops but uncertainty exists concerning the long-term effects of these irrigation practices on the physical and chemical quality of the soil. These effects largely depend on the chemical and physical characteristics of the soil, on the climate, and on the possibility of leaching with natural rain or using high-quality water for leaching. A great concern refers to the reduction of water infiltration capacity. This is especially important where reuse is practised on poorly structured soils and the drainage water has $SAR > 15\ (mmol\ l^{-1})^{1/2}$. However, the capability to predict changes in soil infiltration and permeability is still insufficient.

Long term effects on soil salinization are often considered with simulation models (Minhas *et al.*, 2006; Oster *et al.*, 2012). However, the existing knowledge is still limited. Soil variability in space and irrigation variability both in time and space produce large uncertainty in predictions. Soil salinity under a cyclic strategy of application will fluctuate more, both spatially and temporally, than if using a blending strategy. Predicting or anticipating plant response and effects on the soil would be more difficult when cyclic application is used. However, management strategies must be selected that keep the average root-zone salinity levels within acceptable limits.

Another cause of uncertainty refers to elements such as the boron and chloride contained in drainage water that may produce more long-term detrimental effects than salinity. Furthermore, the reuse of drainage water poses a long-term problem relative to the potential for accumulation of heavy metals in plants and soils. These metals can be toxic to human and animal consumers of the crops. Nevertheless, there is only limited potential for using prediction models to estimate long-term impacts.

Monitoring soil salinity, leaching, and drainage adequacy is therefore paramount to evaluate the long-term impacts from using saline waters, either groundwater or drainage water (Shahid *et al.*, 2013). Monitoring and evaluation should pay attention to:

- The dynamics of salts throughout the soil profile for detecting temporal changes in salinity levels, particularly to identify when salt buildup is steadily increasing.
- The functioning and performance of the drainage system, including observations of drainage outflows and salts transported with the drainage water.
- The irrigation performance, mainly relative to the uniformity of water distribution and the leaching fractions actually applied.
- The irrigation schedule with respect to the satisfaction of irrigation and leaching requirements, and the related constraints due to delivery, or other restrictions that may hamper appropriate irrigation management.
- Sampling EC_e and EC_{iw} throughout the irrigated area to identify the occurrence of problem areas requiring specific water management.
- Sampling for specific ions that may be present in the irrigation water that could have toxicity effects or create health risks, as for heavy metals.
- Follow-up impacts from using saline water such as changes in groundwater quality, plant ecosystems, wetlands, or in riverbed fauna and flora.

New approaches for laboratory and field techniques are required (e.g., Rhoades *et al.*, 1999; Wallender and Tanji, 2012). Environmental impact assessment methodologies for irrigation and drainage projects may also be adapted for surveying and monitoring areas where water of inferior quality, such as saline and wastewater, is used for irrigation.

Wastewater Reclamation and Recycling

Wastewater/Effluent Characteristics

General wastewater characteristics

Municipal wastewater mainly comprises water with relatively small concentrations of suspended and dissolved organic and inorganic solids. Organic substances include carbohydrates, lignin, fats, soaps, synthetic detergents, proteins, and their decomposition products, as well as various natural and synthetic organic chemicals from the process industries. Typical domestic wastewater can be classified as strong, medium, or weak, depending on the concentration of the major constituents. Chemical oxygen demand is 1000, 500, and 250 mg l^{-1}, respectively, for strong, medium, and weak wastewater (Sincero and Sincero, 2003). In arid and semiarid countries, domestic water use is often fairly low, so sewage tends to be very strong.

Municipal wastewater also contains a variety of inorganic substances, including heavy metals, which can have phytotoxic effects and health impacts, thus limiting reuse in agriculture.

Microbiological characteristics – Pathogens

From the point of view of human health, the contaminants of greatest concern are the pathogenic micro- and macroorganisms. Pathogenic viruses, bacteria, protozoa, and helminths may be present in municipal wastewater and will survive in the environment for long periods. At one time, coliforms were thought to be exclusively of intestinal origin, but it is now known that some are free living in the environment and are associated with soil and freshwater. Current practice uses *Escherichia coli* and other fecal indicator organisms, including intestinal *Enterococcus*, to ascertain levels of fecal pollution in water, with their numbers usually being given in the form of fecal coliforms (FC) per 100 ml of wastewater. Although these organisms may not be pathogenic, there is however well-documented correlation with deleterious health effects whenever exposed to measureable levels of fecal indicator organisms.

Pathogenic organisms give rise to the greatest health concern in the use of wastewaters. In areas of the world where helminthic diseases caused by *Ascaris* and *Trichuris* spp. are endemic in the population, and where untreated sewage is used to irrigate salad crops or vegetables eaten uncooked, transmission of these infections is likely to occur through the consumption of such crops. Further evidence was provided to show that cholera could be transmitted through the same pathway. Indian studies have shown that farmworkers exposed to sewage wastewater in areas where *Ancylostoma* (hookworm) and *Ascaris* (nematode) infections are endemic have significantly higher levels of infection than other agricultural workers. More detailed information on health risks and vector-borne diseases are given by WHO (2006a–c, 2011) and Mara and Sleigh (2010a,b). They can be summarized as follows:

- high risk (high incidence of excess infection) due to helminths (*Ancylostoma*, *Ascaris*, *Trichuris*, and *Taenia*);
- medium risk (low incidence of excess infection) due to enteric bacteria (*Vibrio cholera*, *Salmonella typhosa*, and *Shigella*); and
- low risk (low incidence of excess infection) related to enteric viruses (viral diarrheas and hepatitis A).

The main microbiological parameters that are particularly important from the health point of view when characterizing wastewaters (Pereira *et al.*, 2009) are summarized in **Table 3**.

Table 3 clearly shows that there is a wide variety of pathogens present in wastewater, depending upon the region concerned. These pathogens are the cause for a variety of diseases; some of them are of high risk for human health care workers and consumers of produces. Moreover, their survival time in water may be very large. These conditions imply appropriate care when treating and using wastewater.

Xenobiotics

Xenobiotics are either naturally occurring or synthetic compounds that interfere with the functioning of endocrine systems causing unnatural responses. For that reason they are receiving growing attention. Xenobiotics include

Table 3 Main pathogenic parameters relative to wastewaters

Pathogens	*Survival time*	*Presence in wastewater*
Coliforms and fecal coliforms (*Citrobacter*, *Enterobacter*, *Klebsiella*, *Escherichia coli*)	Up to 60 days in water and 70 days in the soil	*E. coli* count is a main indicator
Fecal *Streptococci* (*Streptococci bovis*, *Streptococci equines*, *Streptococci faecalis*)	–	Occur both in man and in other animals
Clostridium perfringens	Survival characteristics similar to viruses or even helminth eggs	Useful in wastewater quality reuse studies
Salmonella spp. (*S. typhi* agent for typhoid)	If removal of Salmonellae is achieved Shigellae and *Vibrio cholera* are probably also removed	Typical in a tropical urban sewage
Enteroviruses: Poliomyelitis and Meningitis, and respiratory infections	May attain 120 days in water	Especially under tropical conditions
Rotaviruses: Gastrointestinal problems	More persistent than enteroviruses	Removal in parallel with that of SS, virus are solids-associated
Intestinal Nematodes: Ascaris lumbricoides	Several months	Infections can be spread by effluent reuse practices

Source: Reproduced from Mara, D., Cairncross, S., 1989. Guidelines for the Safe Use of Wastewater and Excreta in Agriculture and Aquaculture. WHO and UNEP, Geneva and Pescod, M.B., 1992. Wastewater treatment and use in agriculture. FAO Irrigation and Drainage Paper 47. Rome: FAO.

pharmaceuticals (e.g., antibiotics as trimethoprim and erytromycine; analgesics and antiinflammatory drugs as codein, ibuprofen, and diclofenac), plus personal care products (e.g., fragrances, sunscreen agents), pesticides, and disinfectants. Some of these compounds, for example, pentabromobiphenylether, 4-nonylphenol, C_{10}–C_{13} chloroalkanes, and the di(2-ethylhexyl)phthalate (DEHP), have been listed as priority hazardous substances in the field of water policy by the European Directive on Environmental Quality Standards (Directive 2008/105/EC). WHO (2011) also identified some of the above-mentioned xenobiotics through the hazard identification process.

In wastewater treatment plants (WTP), hydrophobic compounds are adsorbed into the sludge, whereas persistent hydrophilic compounds remain in the treated effluents. Whenever these compounds, their metabolites, or transformation products are not removed during wastewater treatment process, they may enter the aquatic environment. As a result, increased attention is being given to the use of reclaimed water to avoid the introduction of xenobiotic compounds into the environment, which is highly relevant in areas where reclaimed water is used for irrigation.

Graywater

Graywater (GW) is defined as the urban wastewater that includes water from baths, showers, hand wash basins, washing machines, dishwashers, and kitchen sinks, but excludes streams from toilets (Santos *et al.*, 2012). GW is an important alternative source of water as it makes up the largest volume of the waste flow from households, and it has a nutrient content that can be beneficially used by crops, and also has a low pathogen content (WHO, 2006c). Owing to the low levels of pathogens and nitrogen, reuse and recycling of GW is receiving more and more attention (Li *et al.*, 2008) as it can be used for any purpose provided it is treated to the desired quality standard. The treatment system varies based on the site conditions and GW characteristics.

The design of a graywater reuse system primarily depends on the quantity to be treated and reuse applications (WHO, 2006c). The reclaimed graywater should fulfill the four criteria (hygienic safety, esthetics, environmental tolerance, and economical feasibility) for reuse. One should also keep in mind that different reuse applications require different water quality specifications and thus demand different treatments varying from simple processes to more advanced ones.

Various studies show the usefulness and limitations of GW for irrigation. Rodda *et al.* (2011) showed that irrigation with GW increased plant growth and yield relative to crops irrigated with tap water. However, the soil irrigated with GW showed increased EC and increased concentrations of metals over time, coupled with an increase in sodium and metal concentrations in crops. Accumulation of surfactants and sodium in soil may also occur due to GW reuse, then affecting adversely agricultural productivity and environmental sustainability. Travis *et al.* (2010) verified that GW could change soil properties impacting the movement of water within the soil and the transport of contaminants in the vadose zone. As for the drainage reuse referred before, appropriate monitoring is required to support further expansion of GW reuse in irrigation and a better definition of treatment requirements.

Wastewater Treatment

General aspects

An appropriate degree of treatment needs to be provided to raw municipal wastewater before it can be used for agricultural and landscape irrigation, or other uses. The required quality of effluent will depend on the proposed water uses, crops to be irrigated, soil conditions, and the irrigation system.

The best available wastewater treatment for agricultural uses is that which allows meeting the recommended microbiological and chemical quality guidelines at low cost, minimizes operational and maintenance requirements, and keeps nutrients in the reclaimed water. Simplicity and robustness of the treatment process is even more important in developing countries. Pathogen removal is a primary concern (Asano *et al.*, 2006; WHO, 2006c).

Irrigation with effluent directly from the treatment plant is generally not feasible and some form of storage of the treated effluent is necessary. Additional benefits can result from storage in reservoirs but their management is particularly demanding because of the need to manage both water quantity and quality (Kfir *et al.*, 2012).

Conventional Wastewater Treatment

Conventional wastewater treatment consists of a combination of physical, chemical, and biological processes and operations to remove solids, organic matter, and, sometimes, nutrients from wastewater (**Figure 2**).

Different degrees of treatment can be considered:

1. Preliminary treatment: The objective is the removal of coarse solids and other large materials from the raw wastewater. Treatment includes coarse screening, grit removal, and trituration.
2. Primary treatment: The objective is the removal of settable organic and inorganic solids. Large fractions of the total suspended solids, oils, and grease are removed but only a fraction of the biochemical oxygen demand (BOD_5, when the test is carried out during 5 days) is removed. If coagulants are used, particulate and colloidal matter are removed together with heavy metals, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs). This may be considered a sufficient treatment if the wastewater is to be used to irrigate crops that are not consumed by humans or to irrigate orchards, vineyards, and some processed food crops as discussed in the Section Management Strategies for Minimizing Health Hazards in Wastewater Use in Irrigation.
3. Secondary treatment: The objective here is to remove the residual organics (soluble BOD_5) and suspended solids. It often involves the removal of biodegradable dissolved and colloidal organic matter using aerobic biological treatment processes. When coupled with a disinfection step such as chlorination, these processes can provide substantial removal of bacteria and viruses. The use of membrane bioreactors (MBR), coupling of a membrane to a bioreactor,

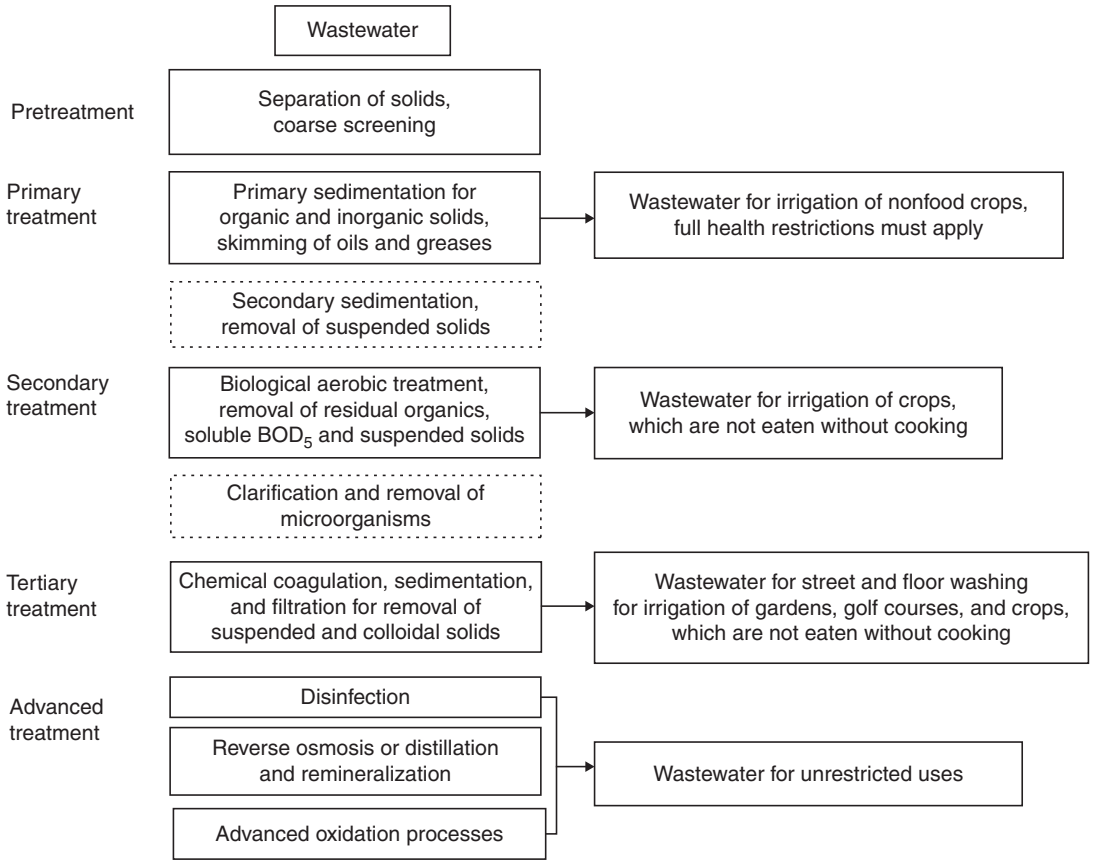

Figure 2 Conventional wastewater treatment and related conditions for water reuse. Modified from Pereira, L.S., Cordery, I., Iacovides, I., 2009. Coping with Water Scarcity. Addressing the Challenges. Dordrecht: Springer, p. 382. Boxes with stippled borders refer to supplemental treatments.

allows achieving an effluent that can be reused without restrictions in irrigation (Fatone *et al.*, 2011).

4. Tertiary treatment is employed when specific undesirable wastewater constituents cannot be removed by secondary treatment, for example, additional suspended solids and refractory organic chemicals (resistant to be broken down through conventional treatment processes).
5. Advanced treatment aims at unrestricted water use, namely in irrigation. It is required because secondary effluents commonly still contain low levels of pathogens, nutrients, and dissolved solids. It includes membrane technology, ultra-/nanofiltration, or reverse osmosis (RO) as well as water remineralization RO membrane filtration. This has been accepted as a proven technology to achieve the quality required for unlimited irrigation reuse (Oron *et al.*, 2008). However, its application is limited due to the requirement for extensive pretreatment along with the associated high operational and maintenance costs. Meanwhile, low-pressure RO is emerging as an alternative to the conventional method. Advanced oxidation processes are considered a highly competitive treatment for removal of refractory organic chemicals. These processes include photochemical degradation, photocatalysis, and chemical oxidation processes. Disinfection normally uses a chlorine solution but ozone and ultraviolet irradiation can also be used.

Natural/biological treatment systems and present advances

Natural/biological treatment systems consist of the following:

1. Stabilization ponds, which according to the metabolic regime present, can be classified as anaerobic, facultative, aerobic or maturation, and aerated ponds. Dissolved or suspended organic matter is metabolized by heterotrophic bacteria with uptake of oxygen, whereas dissolved oxygen is replaced through photosynthetic oxygen produced by microalgae.
2. Overland treatment of wastewater, where the effluent is distributed over gently sloping grassland on fairly impermeable soils, and it moves evenly down the slope to collecting ditches. Suspended and colloidal organic materials are then removed by sedimentation and filtration through the surface grass and organic layers. Pathogens are also removed at levels comparable with conventional secondary treatment systems, without chlorination. The impact on groundwater should be considered in the case of highly permeable soils.

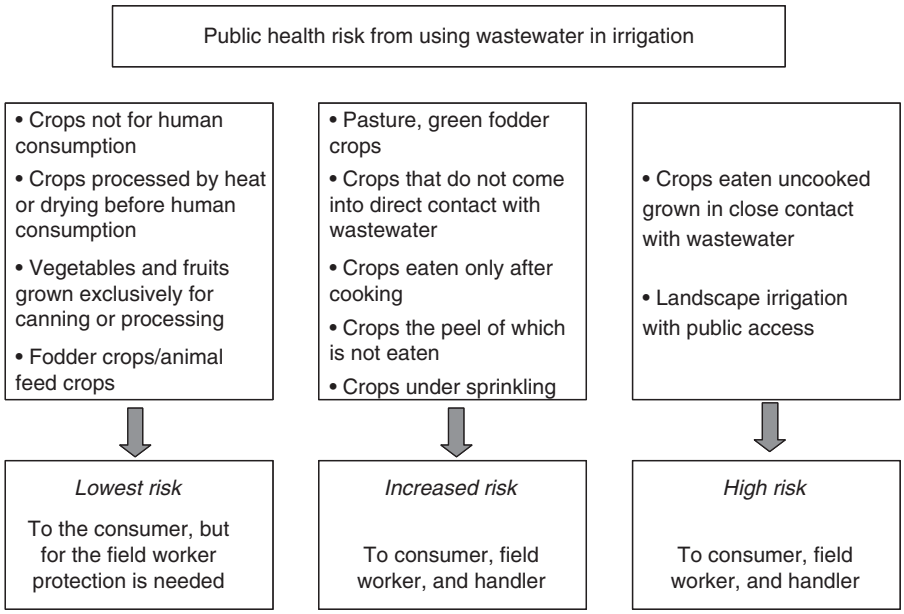

Figure 3 Levels of health risk for consumers and workers due to wastewater use in irrigation. Adapted from Westcot, D.W., 1997. Quality control of wastewater for irrigated agriculture. FAO Water Report 10. Rome: FAO and Pereira, L.S., Cordery, I., Iacovides, I., 2009. Coping with Water Scarcity. Addressing the Challenges. Dordrecht: Springer, p. 382.

3. Wetland treatment systems, where treatment occurs in maturation ponds that incorporate floating, submerged, or emergent aquatic species (macrophytes). Floating macrophytes, desirably having large root systems and very efficient nutrient extraction, include the *Eichornia crassipes* and the *Ceratophyllum demersum*. In wetlands having emergent macrophytes, for example, *Phragmites communis* and *Scirpus lacustris*, aerobic treatment takes place in the rhizosphere as oxygen passes to it from the atmosphere through leaves, stems, and roots, whereas anoxic and anaerobic treatment takes place in the surrounding soil. Nutrients and heavy metals can be removed by plant uptake.
4. Constructed wetlands (CW) have the appearance of a natural wetland habitat and employ many of the biological processes found in natural wetland ecosystems. CW can produce a biologically treated effluent with sufficiently low pathogen content to be safely used for irrigation. As these systems can be constructed from local materials and are simple to operate and maintain, they have the potential to be applied in a variety of countries (Tanaka *et al.*, 2011). Removal processes depend on CW type/configuration and inflow loading (Vymazal and Kröpfelová, 2008). Operation and maintenance activities are essential to guarantee an appropriate performance of CW, including water-level control, weeds control, and plant inspection (Galvão *et al.*, 2009).

Management Strategies for Minimizing Health Hazards in Wastewater Use in Irrigation

Pathogens brought with the wastewater can survive for many days in the soil or on the crops. Thus, a potential for disease transmission exists when wastewater is used for irrigation. Factors influencing transmission of disease include the degree of wastewater treatment, the crops grown, the irrigation method used to apply the wastewater, and the crop and harvesting practices adopted (Westcot, 1997). These factors define the degree of public health risk as depicted in **Figure 3**. Examples of crops representing low risk include olive trees, date palms, and energy crops.

The risk of infection of field workers relates to their direct contact with the crop or soil in the area where wastewater is used. This risk directly relates to the level of protection needed for field workers. Workers safety requires adoption of preventive measures against infection. The following risk situations for field workers are identified (Westcot, 1997):

1. Low risk of infection:
   - mechanized cropping practices;
   - mechanized harvesting practices;
   - irrigation ceasing long before harvesting; and
   - long dry periods between irrigations.
2. High risk of infection:
   - high wind and dust areas;
   - hand cultivation and hand harvesting;
   - moving of sprinkler or other irrigation equipment; and
   - direct contact with irrigation water.

Preventive measures to minimize health hazards for field workers include wearing protective clothing, for example, impermeable boots that prevent any direct skin contact with the wastewater, maintenance of high levels of hygiene, and immunization against infections that are likely to occur.

International guidelines or standards for the microbiological quality of wastewater for irrigation when used for a particular crop do not exist. The standards and guidelines for the quality of wastewater used for irrigation are focused on effluent standards at the wastewater treatment plant, rather than at the point of use. These standards are often used for

Table 4 Health-based targets for wastewater use in agriculture

Exposure scenario	*Health-based target (DALY[a] per person per year)[b]*	*Log_{10} pathogen reduction needed[b]*	*Number of Helminth eggs per litre[c,d]*	Escherichia coli *(number per 100 ml)*
Unrestricted irrigation	$\leq 10^{-6}$			$<10^3$
Lettuce		6	≤ 1	Relaxed to $<10^4$ for high-growing leaf crops or drip irrigation
Onion		7	≤ 1	
Restricted irrigation	$\leq 10^{-6}$			$<10^5$
Highly mechanized		3	≤ 1	Relaxed to $<10^6$
Labor intensive		4	≤ 1	When exposure is limited or regrowth is likely
Localized (drip) irrigation	$\leq 10^{-6}$			
High-growing crops		2	No recommendation[e]	
Low-growing crops		4	≤ 1[d]	

[a]Disability adjusted life years.
[b]The health-based target can be achieved, for unrestricted and localized irrigation, by a 6–7 log unit pathogen reduction (obtained by a combination of wastewater treatment and other health protection measures). For restricted irrigation, it is achieved by a 2–3 log unit pathogen reduction.
[c]When children under 15 years are exposed, additional health protection measures should be used (e.g., treatment to ≤ 0.1 egg l^{-1}).
[d]The mean value of ≤ 1 egg l^{-1} should be obtained for at least 90% of samples.
[e]When no crops to be picked up from the soil.
Source: Adapted from WHO, 2006b. WHO Guidelines for the Safe Use of Wastewater, Excreta and Greywater, vol. II. Wastewater Use in Agriculture. Geneva: World Health Organization and WHO, 2006c. WHO Guidelines for the Safe Use of Wastewater, Excreta and Greywater, vol. IV. Excreta and Greywater Use in Agriculture. Geneva: World Health Organization.

process control at wastewater treatment plants. On the basis of an epidemiological review, WHO adopted water quality guidelines for wastewater use in agriculture as shown in Table 4. These guidelines are for the microbiological quality of treated effluent from a wastewater plant when that water is intended for irrigation.

It is advisable to utilize the WHO (2006a–c) guidelines for controlling the quality of water used in irrigation (Table 4). Using them as irrigation standards would help to:

- identify the areas currently being contaminated;
- reduce the disease infection risk until suitable wastewater treatment is adopted;
- improve the basic health level in rural areas; and
- provide indication and data of unsatisfactory areas to assist in planning for wastewater management.

Using the helminth standard throughout all cropping systems aims at increasing the level of protection for agricultural workers, who are at high risk of intestinal nematode infection (WHO, 2006b). It is assumed that if the recommended helminth egg limit could be reached, then equally high removals of all protozoa would be achieved. No bacterial guidelines were considered by WHO for protection of agricultural workers because there was little evidence of such a risk to workers, and some degree of reduction in bacterial concentration would be achieved with efforts to meet the helminth levels. Guidelines shown in Table 4 should be adapted according to local requirements and specifications.

As urban populations grow enormously, the degree of river and irrigation water supply contamination in developing countries will likely increase. Pressure will also increase to use partially treated wastewater for irrigation until adequate treatment facilities can be constructed. In addition, predicting long-term effects of wastewater use is yet not supported by sufficient research (Xu *et al.*, 2010). Thus, there is an immediate need to control wastewater use in high-risk cropping systems such as vegetable crop production. The guidelines proposed by WHO (2006a–c) could be applied in areas where wastewater is utilized directly for irrigation or where use is indirect, for example, where contaminated river water, including when a treatment plant exists, is diverted for irrigation.

Indicative expected removal levels of pathogens are shown in Table 5 for various treatment processes. Results depend not only upon the treatment, but also on the time of detention (Westcot, 1997; Pereira *et al.*, 2009). Further disinfection may be required for products that are eaten fresh (Bichai *et al.*, 2012).

Crop Restrictions and Irrigation Practices

To minimize the health risk from using wastewater in irrigation, the prime approach is to treat the wastewater to the level recommended above. However, untreated or insufficiently treated wastewaters are still used for irrigation when uncontrolled flows are used. Then, the application of crop restrictions is a required measure to protect the consumer and to protect public health. Crop restrictions focus on salad or vegetable crops that are normally eaten raw as indicated before. Unfortunately, in countries where institutional arrangements and enforcement of standards are usually not strong enough, crop restrictions are not effectively enforced and do not ensure that unsafe food products are not presented to the consuming public.

Table 5 Indicative log unit reductions or inactivation of pathogens achieved by selected wastewater treatment processes

Treatment process	*Log unit pathogens removals*[a]			
	Viruses	*Bacteria*	*Cysts*	*Helminth eggs*
Low-rate biological processes				
Waste stabilization ponds	1–4	1–6	1–4	1–3
Wastewater storages and treatment reservoirs	1–4	1–6	1–4	1–3
Constructed wetlands	1–2	0.5–3	0.5–2	1–3
High-rate processes				
Primary treatment				
Primary sedimentation	0–1	0–1	0–1	0 to <1
Chemically enhanced primary treatment	1–2	1–2	1–2	1–3
Secondary treatment				
Activated sludge + secondary sedimentation	0–2	1–2	0–1	1 to <2
Trickling filters + secondary sedimentation	0–2	1–2	0–1	1–2
Aerated lagoon + settling pond	1–2	1–2	0–1	1–3
Tertiary treatment				
Coagulation/flocculation	1–3	0–1	1–3	2
High-rate granular or slow-rate sand filtration	1–3	0–3	0–3	1–3
Dual-media filtration	1–3	0–1	1–3	2–3
Membranes	2.5 to >6	3.5 to >6	>6	>3
Disinfection				
Chlorination	1–3	2–6	0–1.5	0 to <1
Ozonation	3–6	2–6	1–2	0–2
Ultraviolet radiation	1 to >3	2 to >4	>3	0

[a]The log unit reductions are $\log_{10}$ unit reductions. A 1 log unit reduction = 90% reduction; a 2 log unit reduction = 99% reduction; a 3 log unit reduction = 99.9% reduction; and so on.

Source: Adapted from WHO, 2006b. WHO Guidelines for the Safe Use of Wastewater, Excreta and Greywater, vol. II. Wastewater Use in Agriculture. Geneva: World Health Organization.

Crop restrictions need a strong institutional framework and the capacity to monitor and control compliance with the regulations (Pereira *et al.*, 2009). Regulations and governance on the use of wastewater, namely for irrigation, are required (Hanjra *et al.*, 2012). Planning, management, and operation of reservoirs for wastewater reuse are essential in terms of wastewater quality and related reuse performance (Kfir *et al.*, 2012).

The following factors favor the adoption of crop restrictions:

- A law-abiding society or strong law enforcement.
- Allocation of wastewater is controlled by a public body that has legal authority to enforce crop restrictions.
- The irrigation water conveyance and distribution system is controlled by strong central management.
- There is high demand and price advantage for the unrestricted crops.
- There is little market pressure in favor of the excluded crops.
- Wastewater is used by a small number of large farms.

Very large, dispersed irrigation schemes and those having poor or weak management make it difficult to enforce crop restrictions. Difficulties also occur when producers are mainly small farmers and the market prices do not favor adopting lower risk crops. In many developing countries, when wastewater, including untreated effluent, is discharged directly to surface waters and these are diverted downstream for irrigation purposes there is a widespread distribution of the wastewater and crop restriction becomes extremely difficult.

Irrigation practices should be designed according to the quality of used wastewater. Salinity hazards associated with wastewater are considered in the Section Crop Irrigation Management Using Saline Water (**Table 2**). Aspects referring to the control of health hazards were discussed in the precedent sections. However, the selection of methods of irrigation with wastewater to comply with guidelines for controlling health risks requires particular attention. Irrigation methods differ on several aspects as summarized in **Table 6** They mainly concern:

- The probability of direct contact of workers with the irrigation water, thus referring to the need for adopting more stringent preventive measures.
- The direct contact of the water with the harvestable yield, thus implying the need for a careful implementation of consumer protection measures, including crop restrictions.
- The foliar contact with the water that may cause phytotoxic problems.
- The capability for avoiding salt concentration in the crop root zone, which would require measures to avoid soil degradation (Muyen *et al.*, 2011; Xu *et al.*, 2010) as referred above in relation to the use of saline water.

Drip irrigation is often preferred. Then filtering is essential for appropriate functioning of the system. Media filters may be recommended due to their ability to remove turbidity and the ability to recover dissolved oxygen (Elbana *et al.*, 2012).

Aspects relative to health risk reduction have been discussed in the sections above and may be found in several references, such as WHO (2006a), Pescod (1992), and Westcot (1997). Toxicity hazards to the crops (Ayers and Westcot,

Table 6 Evaluation of the irrigation methods for irrigation with wastewater

Irrigation methods	*Basin irrigation and border irrigation*	*Corrugated basin irrigation*	*Furrow irrigation*	*Sprinkler irrigation*	*Micro irrigation: drip and subsurface irrigation*	*Microirrigation: microsprinkling and microspray*
Human contact (health hazard)	Likely to occur, mainly when water is controlled manually. Preventive measures including clothing requirements	Likely to occur when water is controlled manually, less with automation. Preventive measures including clothing are required	Likely to occur, when water is controlled manually, less when automation is adopted	Workers may have contact with wetted equipment. Small droplets will inevitably be spread by wind, so workers will always be at risk	Not likely to occur except contact with wetted irrigation equipment	Generally workers are not in the field when irrigating but they may have contact with wetted equipments. Small drops will inevitably be spread by wind, so workers will always be at risk
Contact with fruits and harvestable yield (contamination hazard)	Not occurring for tree crops and vines, most horticultural and field crops. May occur for low vegetable crops such as lettuce and melon	Not likely to occur because crops are grown on ridges	Not likely to occur because crops are grown on ridges	Fruits and harvestable yield are contaminated	Not likely to occur	Fruits and harvestable yield of vegetable crops may be contaminated. Less likely for under-tree irrigation with no wind
Salt accumulation in the root zone (salinity hazard)	Not likely to occur except for the underirrigated parts of the field when uniformity of water application is very poor	Salts tend to accumulate on the top of the ridge. Leaching before seeding or planting is required for assuring germination and plant establishment	Salts tend to accumulate on the top of the ridge. Leaching is required before seeding/planting	Not likely to occur except for the underirrigated parts of the field resulting from low uniformity of water application	Not likely to occur except for the underirrigated parts of the field resulting from low uniformity of water application	Not likely to occur except for the underirrigated parts of the field resulting from low uniformity of water application
Foliar contact (toxicity hazard)	Possible for bottom leaves in low crops (e.g., lettuce and melon) and fodder crops during first stage of annual crops	Exceptionally because crops are grown on ridges and water flows in furrows between them	Exceptionally because crops are grown on ridges	Severe leaf damage can occur affecting yields. Edible leaves would be contaminated	Not likely to occur	Severe leaf damage can occur definitely affecting yields of annual crops, but not for irrigation of trees and vines if drops are large enough and jets are oriented to the soil. Hazardous for edible leaves

Source: Reproduced from Pereira, L.S., Cordery, I., Iacovides, I., 2009. Coping with Water Scarcity. Addressing the Challenges. Dordrecht: Springer, p. 382.

1985) mainly require avoiding direct contact between the water charged with toxic ions and the crop leaves and other sensitive parts of the crop. Dilution of ion concentrations by mixing charged waters with freshwater is generally more costly than to select an irrigation method where such foliar contact is minimized.

Salts in wastewater used for irrigation are a source of soil pollution (Kalavrouziotis and Koukoulakis, 2012). The salt accumulation in the root zone is generally controlled by leaching of the salts from the root zone naturally when rainfall is abundant, or by applying a leaching fraction with the irrigation water. Leaching is discussed in the Section Leaching Requirements and Strategies for Controlling Impacts on Soil Salinity. Appropriate application of a leaching fraction depends on the irrigation method and the performance of the irrigation system. Practising overirrigation to be sure that salts are leached down from the root zone is common but leads to excessive percolation to the groundwater and may cause waterlogging. The groundwater quality can be degraded. Drainage has to be considered. However, problems may be controlled easily if the irrigation system is designed carefully allowing for control of volumes applied and for a uniform distribution of water over the field.

In summary, the safe use of wastewater in irrigation requires not only compliance with guidelines for the control of health risks, but also well-designed and efficiently managed irrigation systems. Several case study examples are provided in the literature (e.g., Oron *et al.*, 1999).

Monitoring and Control for Safe Wastewater use in Irrigation

Developing a program to promote safe crop production areas should occur alongside and as an alternative to crop restrictions. This can be achieved with a phased process as listed below:

1. Development and implementation of a sound program for water quality monitoring to evaluate the existing levels of contamination in the water and its use, including
   - appropriate recognition of observation areas and sites;
   - selection of water quality and contamination indicators;
   - selection of analytical methods and participating laboratories;
   - identification of sampling techniques; and
   - selection of field sites, considering
     - the water sources,
     - crop patterns, and
     - cropping and irrigation practices.
2. Conducting the field water quality monitoring program, evaluating the water quality data, and developing procedures to assess the levels of contamination. In addition, it is advisable to follow-up soil salinity aiming at protecting the soil resource.
3. Developing a database aimed at defining safe production areas and to control or regulate contaminated water use in vegetable or other high risk production areas.
4. Through the combination of field monitoring and exploring the database, to install certification programs that assure consumers on the quality and safety of production methods applied in a given area. The last phase is developing mechanisms to regulate the use of potentially contaminated water on high-risks crops, thus also supporting certification programs.

A follow-up of farmers' attitudes and behavior relative to the use of wastewater, particularly when it does not comply with the required guidelines, is also important because changes in water use aimed at health safety of consumers and workers can only be effective with the involvement of farmers and their institutions (e.g., Qadir *et al.*, 2010).

Desalination as an Alternative Source of Water for Agriculture

General Aspects and Treatment Processes

The main desalination processes (Fritzmann *et al.*, 2007; Li *et al.*, 2008) are listed below:

1. Thermal distillation (TD): When a saline solution is boiled, the vapor that comes off is pure water and when this is cooled (condensed), the resulting water contains no salt. Three types of thermal distillation units are used commercially, namely, multistage flash, multiple effect distillation, and vapor compression.
2. Electrodialysis (ED): If a current is passed through a saline solution, the different ions (cations and anions) in the solution will carry the current from one electrode to the other by drifting in opposite directions. If an ion-selective membrane is placed in this flow, say an anion-permeable membrane, only the anions will manage to pass through. ED is only an economical process when used on brackish water, and tends to be most economical at TDS levels of up to 4000–5000 mg l^{-1}.
3. RO: This is a membrane separation process in which the pressure of the water is raised above the osmotic pressure of the membrane. No heating or phase change is necessary for this separation, and the major energy requirement is for pressurizing the feed water. Seawater reverse osmosis (SWRO) has emerged as the leading technology for future seawater desalination facilities because of its relatively low energy consumption and produced water cost compared with thermal desalination technologies (Greenlee *et al.*, 2009). However, the perceived costs and energy requirements of seawater desalination continue to be a barrier to its implementation, especially seawater desalination for agricultural use. The stringent boron and chloride standards make the process more energy intensive than desalination for potable use. The total energy consumption by a state-of-the art SWRO facility producing agricultural irrigation water is in the range of 3–7 kWh m^{-3} of produced water (WRA, 2011). A combined seawater desalination process using emerging forward (FO) technology coupled with RO could potentially reduce the energy consumption of the seawater desalination process, and thus lower barriers to its implementation. The FO process is strictly direct osmosis across an RO-type membrane.
4. Desalination can use photovoltaic technology to provide electrical energy to operate standard desalting processes like RO or electrodialysis. Solar desalination has been receiving

considerable interest as it allows producing potable water in a sustainable way, which is particularly important in arid areas.

Use in Agriculture, Impacts, and Constraints

In the past, the high cost of desalinating and the energy required have been the major constraints on large-scale production of fresh water from brackish waters and seawater. However, desalinated water is becoming more competitive because desalinating costs are declining and the costs of surface water and groundwater are increasing. Nevertheless, the costs of desalinating water do not allow its full use in irrigated agriculture, with the exception of intensive horticulture for high-value cash crops, such as vegetables and flowers, mainly grown in greenhouses (Martínez-Beltrán and Koo-Oshima, 2006).

However, besides cost, there are other important drawbacks that prevent the wide use of desalinated water in agriculture, because when essential nutrients, including Ca, Mg, and S, removed during RO, are not reintroduced as observed by Ben-Gal *et al.* (2009) serious deficiencies in crops occur. The deficiency of calcium may harm the development of terminal buds and of root apical tips (Yermiyahu *et al.*, 2007), whereas magnesium is vital to the photosynthesis and protein synthesis operations of plants. Irrigation with low-magnesium-content water (10 mg l^{-1}) resulted in a decrease in leaf magnesium and chlorophyll contents, and the fruit produced was lacking in the basic nutrients like magnesium, calcium, and sulfate. This implies the need for additional fertilization (Birnhack and Lahav, 2007). Moreover, the very low buffering capacity of desalinated water can cause sudden changes in pH during fertilizer addition and can have a great impact on nutrient availability and ultimately on agricultural productivity (Yermiyahu *et al.*, 2007). In addition, the high levels of boron (B) have been found to cause boron toxicity in a number of B-sensitive crops (Yermiyahu *et al.*, 2007).

To overcome these negative impacts there are two possible strategies, either previously mineralizing the desalinated water, or blending desalinated and natural water in order to achieve the required quality. Ben-Gal *et al.* (2009) evaluated both the strategies for supplying these nutrients: Blending 30% saline water with 70% desalinated water brought Ca, Mg, and S minerals to satisfactory levels, whereas producing water with salinity of EC = 1.35 dS m^{-1} which led to satisfactory yields. These researchers noted that the environmental cost of the increase in irrigation water salinity through blending was substantial. Summarizing, fertilizer management must be carefully defined to avoid problems because of the absence of Ca, Mg, and other elements as well as to avoid problems of inhibition of use of nutrients due to unbalanced composition of the soil water and soil extract.

The main environmental impacts of water desalination relate to the production of a flow of brine containing the salts removed from the raw water. This needs to be disposed. Environmentally safe disposal depends mainly on the site of the treatment plant. If situated near the sea or close to brackish environments, such as estuaries, brine disposal is comparatively easier than that from inland desalinating facilities. In addition, it is worth mentioning that the energy consumption associated with the desalination process has an indirect environmental impact on greenhouse gas emissions.

Concluding Remarks

The use of low quality waters in agriculture, either drainage water or groundwater from low-quality aquifers, as well as the reuse of wastewater or desalinated water, need appropriate practices for controlling the impacts on the environment, on the crops, and particularly on human health. Crops, soil, and irrigation must be managed in agreement with characteristics of the used water in relation to the sensitivity of the crops, the fragility of the soils and environment, and, in case of wastewater, to avoid health consequences for workers and consumers. When appropriate technologies and management are applied, large benefits result from recycling and desalination for agricultural use helping to cope with water scarcity and drought. As described in this article, it is possible to develop strategies based on appropriate resource management and the adoption of the best available technologies, which support human health control, minimizing environmental impacts, and achieving positive farm returns, thus leading to sustainable development. Nevertheless, it is definitely required to develop educational and awareness programs that may make easy the adoption of best management practices and acceptability by the consumers.

Glossary

Confined animal feeding operations (CAFOs) Raising animals in confined areas. All feed is brought to the animal.
Critical source areas Areas of a field, farm, or catchment that account for the majority of nutrient and sediment loss.
Ecosystem services Benefits people obtain from ecosystems. These include provisioning services such as food and water; regulating services such as flood and disease control; cultural services such as spiritual, recreational, and cultural benefits; and supporting services such as nutrient cycling.
Farm dairy effluent Liquid waste material derived from washing down cattle excreta from farm dairies and yards. It is usually land applied to capture its nutrient value.
Manure Dung collected from animal housing and applied to land for its nutrient value.
Slurry Semi liquid waste from animal confinement facilities that contains a high concentration of sediment. It is stored in tanks or ponds before land application for its nutrient value.

Introduction

The requirement to feed an expanding human population and make a profit has driven the expansion and intensification of agricultural production systems. The two main production systems, cropping and livestock, present different challenges to water quality due to contrasting geographic and climatic factors and management decisions. For example, unless animal manure is spread onto cropped fields, issues associated with fecal contamination of waterways is generally restricted to livestock or integrated crop–livestock systems. However, common among both production systems are losses of nitrogen (N), phosphorus (P), and sediment. Their effects vary from direct toxicity (e.g., nitrate-N; NO_3^--N) to indicators of, for example, poor esthetic and recreational values (N and P stimulation of periphyton (algae)) or inhibition of fish spawning (suspended solids). This article examines and highlights many of the processes, transport systems, and management decisions that exacerbate N, P, and sediment losses at a local scale and reviews some of the systems, strategies, and policy that influence these losses at a regional or national scale.

Water Quality Effects of N, P, and Sediment

The quality of stream water is strongly influenced by factors such as catchment bedrock, climate, soil type, and land use. Effects can be seen locally or downstream in larger rivers and lakes due to the cumulative effects of upstream inputs. Development of land ultimately results in a greater load of nutrients (N and P) and sediment entering streams, rivers, and lakes that stimulates plant growth. Research on the North American Great Lakes in the 1960s established that phytoplankton growth was driven by P inputs, rather than N or other elements. The same appears to be true for many lakes in Europe and for periphyton growth in streams and rivers worldwide (Hecky and Kilham, 1988; Vollenweider, 1968; McDowell *et al.*, 2009). Nutrient limitation occurs when the ratio of N:P differs from 7:1 (Redfield *et al.*, 1963), whereby, if on a weight basis, more than 7 units of N are present relative to P, biomass is limited by P. However, the Redfield ratio (7N:1P) should always be confirmed by measuring N:P in periphyton biomass.

Once cleared of adjacent trees, streams that were cool and weed free with ample shading become warmer and often choked with periphyton and aquatic weeds (macrophytes). In addition to being esthetically poor, some algae can be toxic and produce offensive odors and tastes in water that requires substantial treatment to be potable or suitable for contact recreation. Increased plant growth and photosynthetic production also causes large diurnal variation in dissolved oxygen and pH (Wilcock *et al.*, 2007). The respiration associated with decaying vegetation may cause dissolved oxygen concentrations to decrease below that necessary for aquatic life, whereas pH may increase in the afternoon, potentially inducing ammonia (NH_3) toxicity. Ammonium-N (NH_4^+) is nontoxic, but as pH increases, the ratio of toxic NH_3:NH_4^+ increases until both are approximately equal at a temperature of 20 °C and a pH of 9.4. A general rule of thumb is that when NH_4^+ concentrations reach 1–2 mg l^{-1}, unionized NH_3 concentrations can become toxic to stream life, especially invertebrates (Hickey and Vickers, 1994). Nitrate, usually the dominant form of N in freshwater (surface and ground), has also been shown to be toxic to invertebrates (Carmargo *et al.*, 2005) and some fish species (e.g., trout; Hickey and Martin, 2009). Consumption of nitrate (e.g., in groundwater used for drinking) has also been linked to methemoglobinemia in infants, whereas nitrite (and nitrosamines) has been linked to an increased prevalence of some cancers (WHO, 1996). This has been the basis of widespread policy aimed at restricting nitrate-N in potable water (e.g., 11.3 mg NO_3^--N, EU, 1991).

The effects of sediment loss are varied. Generally, water becomes more turbid due to light scattering by suspended particles (Davies-Colley and Smith, 2001), which inhibits the ability of fish to detect prey and may damage the respiratory structures of aquatic animals (Ryan, 1991). The deposition of fine sediments in gravel-bed streams can also smother the bed,

decreasing available habitat for invertebrates and fish and decreasing spawning success in native and introduced fish.

Sources of Nutrient and Sediment Loss: System and Regional Effects

Cropland versus Grassland

Agricultural systems can be categorized into cropping or grassland systems with or without animals that either graze forage outdoors or are confined to a barn and supplied feed. Most N and P loss originates as diffuse sources from agricultural production systems due, in part, to the success in identifying and mitigating point sources (Withers *et al.*, 2011). Losses of N, P, and sediment occur via runoff, termed here as the sum of surface runoff and subsurface flow (viz., subsurface runoff or leaching). Surface runoff from forests, grasslands, and other noncultivated soils carries little sediment, so the loss of P, which binds readily to soil and sediment, tends to be dominated by dissolved P, an immediately algal-available form (Sharpley, 1993). In contrast, nitrate, the main form of N loss, is soluble and hence largely lost in subsurface flow, although substantial losses of N can also occur in surface runoff via the erosion and loss of N in particulates.

Under cropping, the generation of N, P, and sediment is a function of inputs (for nutrients), soil and crop type, and their response to cultivation. The quantity, type, and timing of N and P inputs affect the rate at which both nutrients are taken up or lost to runoff. Poor application timing, when the crop is not growing, results in much of the applied N or P being available for loss. Application in forms that are not immediately plant available, or saturation of the soil solution with N or P, can also exacerbate losses. For example, the use of low water-soluble P fertilizers can decrease P losses in surface runoff compared with highly water-soluble superphosphate (McDowell *et al.*, 2010).

The differing yield, root morphology, and growth rates of various crops can be optimized (and crops rotated) so that both N uptake at depth is maximized and the area of soil exposed to surface runoff (and thus erosion of P and sediment) is minimized. The cultivation of crop land greatly increases erosion, and with it the loss of particulate-bound P (60–90% of total P; Sharpley *et al.*, 1995). Some of the particulate-bound P is not readily available but can be a long-term source of P for aquatic biota (Sharpley, 1993). Cultivation also stimulates the mineralization of organic matter, and with it organic N is transformed into nitrate that is potentially available for loss should drainage occur. The quantity of sediment lost from a field can be predicted by models, such as the revised universal soil loss equation (Renard *et al.*, 1997), which includes factors such as slope length, rainfall, soil type, and management. Under the same rainfall intensity and slope, water erosion tends to be greater in soils with a high proportion of silt and very fine sand and low organic matter. Increasing the time a field spends in fallow and the coincidence of either spring snowmelt or strong winds can also result in substantial topsoil loss (Wade and Kirkbride, 1998).

Under grassland, the loss of N, P, and sediment can vary just as much as under cropland. Under a cut and carry system (pasture is cut and removed from site), losses are expected to be very low. However, with the introduction of grazing animals, factors such as animal treading and excretal returns influence losses. Animal behavior and stocking rate can interact with catchment characteristics (e.g., slope or soil type) and exacerbate losses. For N, the main factors driving losses from grazed grassland are animal type and stocking rate as related to urine deposited on the ground. The N content of a urine patch greatly exceeds that required by grasslands, especially for dairy cattle but also red deer and sheep (Hoogendoorn *et al.*, 2011), which results in the surplus being lost should drainage occur (Ledgard *et al.*, 1999). For P, losses relate to soil P concentrations, animal treading, and inputs via fertilizer (see above), manure (covered in the next section), and excretal returns (McDowell *et al.*, 2007). The relative contribution depends on how well or poorly each is managed. For instance, soil P can contribute 80% of annual losses, especially if the soil contains little aluminum and iron oxides or if P concentrations are highly enriched (McDowell and Condron, 2012).

Although most low-producing permanent grasslands tend to lose little nutrients or sediment, high-producing grasslands, such as those often used for dairy farming, are cultivated and resown every 6–10 years. Storage of N as organic N in grassland (despite grazing) is well known. For instance, Whitehead *et al.* (1990) estimated some 600 kg N ha^{-1} had accumulated during grazing of a sward for 15 years. Once cultivated, much of this N could be mineralized and lost. In some cases, grassland is interspersed with a crop intended to be grazed *in situ* over winter or summer should feed be in short supply. However, the urine and dung deposited on a mature forage crop, together with the soil damage caused by treading and removal of the crop canopy, can result in large losses of nutrients and sediment (McDowell *et al.*, 2005).

Confinement versus Grazed Systems

An added complexity found in livestock production systems is the opportunity to intensively utilize housing, for example, confined animal feeding operations (CAFOs). Owing to economics, CAFOs tend to be larger but with less land than grazed operations (McDowell and Kleinman, 2011). The development of intensive and often specialized farming systems as CAFOs has led to regional surpluses of N and P due to imports in fertilizer and animal feed exceeding exports in farm produce (Kellogg *et al.*, 2000). For example, the application of manures and slurry is often guided by advice or regulation based on N content and the N requirement of crops. However, during storage, manure and slurry lose N in gaseous form (NH_3, N_2, and N_2O), lowering the N:P ratio and potentially resulting in oversupply and enrichment of soils with P. The enrichment of manures can be exacerbated by overfeeding of P. For example, Dou *et al.* (2003) surveyed 612 dairy farms in the Northeast USA and observed that dietary P concentrations for lactating cows ranged from 3.6 to 7.0 g kg^{-1} of feed dry matter. The mean concentration (4.4 g kg^{-1}) was about a third greater than that recommended by the National Research Council (2001) but seen as insurance to ensure good reproductive efficiency (Tallam *et al.*, 2005).

One of the first steps in decreasing P losses from CAFOs is, therefore, to balance P inputs with outputs at the farm, catchment, or regional scales. However, a near-zero P balance may maintain only the present rate of P loss if, for example, soil P concentrations are enriched and are above plant requirements (Woolsey *et al.*, 2007). This requires the use of mitigation technologies (see mitigation section), in addition to a negative P balance, to obtain a level of P loss that is environmentally and agronomically acceptable.

Dealing with manure is central to the successful environmental operation of a CAFO. The method, rate, and timing of application all influence losses of N and P. Surface application of manure concentrates P on the soil surface where it is prone to loss by surface runoff. In contrast, a direct ground injection system injects slurries containing $<12\%$ solids below the soil surface, minimizing surface runoff losses but also decreasing NH_3 emissions by up to 60% compared with surface application (Morken and Sakshaug, 1998). Elsewhere on the farm, NH_3 emissions, and hence N left that is available for loss to water, are dominated by manure storage systems, with the highest losses associated with anaerobic lagoons and the lowest losses with pits or bedded packs (Powell *et al.*, 2004).

The loss of N and P from surface-applied manures decreases within time, because application as rainfall washes manure nutrients into the soil. Crusting and invertebrate action also protect N and P from interacting with runoff (Webb, 2001; Kleinman and Sharpley, 2003; Vadas *et al.*, 2007). Hence, if applied at a time when runoff is frequent, losses of N and P can be large. Preedy *et al.* (2001) reported that 1.8 kg ha^{-1} of P was lost in runoff within 7 days of applying dairy slurry to grassland, whereas Mueller *et al.* (1984) reported that dissolved P concentrations in surface runoff decreased by 76% two months after manure was applied.

Moving from confinement to grazing can significantly alter the N loss profile away from manure and toward the high concentrations of NO_3^- that have been shown to leach from urine patches (Di and Cameron, 2000). The low proportion of a field covered, and patchiness in which urine is deposited, means that N-use efficiency is low, as supplemental N fertilizer is needed to ensure uniform sward production. Although the management of N losses from a farm can be addressed via a mass balance approach, factors such as stocking rate hold more relevance in grazed systems due to the dominance of N loss via urine patches. Globally, the literature on grazed farm N balances is varied, with some not accounting for biologically fixed N. However, when N fixation is factored into the mass balance, differences between outputs in grazing and CAFOs are not obvious and obscured by management factors (**Table 1**). Whether or not surplus N will translate into N losses in either system will depend on where and when animals are grazed and fertilizer or manure is applied (**Figure 1**).

For P and sediment, grazing offers some flexibility to maintain low soil test P concentrations and therefore minimize the application of manure (largely dairy shed effluent in grazed systems) and fertilizers. However, grazing operations are also limited by their ability to adjust to poor weather conditions, which can mean that they lose just as much P as a CAFO (**Table 1**). For example, if animals are grazing a field adjacent to a stream, there is a very high potential for runoff to reach the stream. Owing to a high concentration of animals that are rotated around fields on grazed dairy farms, the runoff (especially surface runoff) from a recently grazed field is most likely to be enriched in sediment (from treading damage to wet soils) and P. Furthermore, during spring, inclement weather means that effluent may have to be applied to wet fields potentially resulting in large losses of effluent P (e.g., 2–4 kg P ha^{-1} yr^{-1}; Houlbrooke *et al.*, 2004).

With more animals grazing grassland, erosion rates increase. For instance, Matthaei *et al.* (2006) found that stream beds surrounded by ungrazed tussock grassland had significantly less fine sediment than those with pasture grazed by dairy cattle or red deer. Much of the sediment was derived from the treading of grazing animals on stream banks, which destabilizes soils, causing slumping and loss of soil into stream channels (McDowell *et al.*, 2008). In contrast, stream channels in forested catchments tend to be wider than in grassland catchments, because sediment is temporarily stored by pasture grasses, resulting in narrow and incized channels that release sediment during flood events (Davies-Colley, 1997).

In general, sediment inputs to streams in agricultural catchments without extensive drainage networks may be dominated by sheet and rill erosion from cropland systems (Wischmeier and Smith, 1978) and by bank erosion in grazed pastures. For example, a Danish study found that streambank erosion contributed more than half the annual catchment export, much greater than forested or cropland areas (Laubel *et al.*, 1999). However, the response can also be seasonal with streambank erosion of greater importance than surface runoff or bed erosion in winter when animals were not intensively grazing grassland (due to a lack of grass cover or they were being housed) but less important in spring and autumn when grazing is occurring (McDowell and Wilcock, 2007). In cropland or grassland catchments that are artificially drained, Walling *et al.* (2002) found that 30–60% of sediment came from subsurface drains compared with 6–10% from channel bank erosion. A similar result was found for sediment-associated P entering a stream in an intensively farmed dairying catchment in Southland, New Zealand (McDowell and Wilcock, 2004).

Animal behavior can also contribute to sediment and P losses in grazed systems. Sheep tend to avoid streams, whereas red deer and cattle both like to stand in stream beds and tend to defecate more than when grazing or resting on a field (Collins *et al.*, 2007). Red deer also seek out ephemeral channels and dig them out until a wallowing area is created. This can add substantial P (3–4 kg P ha^{-1} yr^{-1}) and sediment ($>$ 1000 kg ha^{-1} yr^{-1}) to field-scale losses (McDowell, 2009).

A solution, at least for dairy systems where profit is better than grazed drystock farms, is to utilize components of both confinement and grazing farming systems – termed a hybrid farm. McDowell and Kleinman (2011) presented an argument that hybrid-grazing operations have a high degree of flexibility to adjust to catchment and climatic conditions. For example, they can choose to graze or not if grassland fields are too wet and surface runoff losses of P and sediment are likely. Measured data also suggest that less time spent grazing fields minimizes N losses, provided manure- and effluent-handling practices for the off-field part of the operation are well managed (**Table 1**).

Additional evidence shows that even within catchments dominated by grazed grassland, loads of N, P, and sediment vary

considerably among different land use as denoted by stock class (Figure 2). This means that there is considerable scope for improvement, even for land used for dairying, which is perceived to lose more water quality contaminants than other land uses (Davies-Colley and Nagels, 2002). However, mitigation practices that decrease the impact of intensive agriculture on water quality vary in effectiveness and cost depending on a number of site-specific factors. Strategies need to be fully assessed (including cost) and matched to the farming system and catchment so that their efficacy is maximized and cost minimized.

Scope for Improvement

Technologies to Mitigate N, P, and Sediment Losses

Mitigation measures include those that instigate better management of existing resources/inputs, apply amendments to decrease losses, and mitigate losses after they have left the field. Mitigation strategies and expected decreases in sediment and nutrient loss are summarized in Table 2.

Agricultural nutrient management plans (NMPs) quantify nutrient imports and exports within agricultural systems. They provide a means to balance fertilizer inputs with crop nutrient requirements (i.e., outputs), thereby helping to prevent excess application (Genskow, 2012). Routine soil testing can provide a guide for applying nutrients and assist in identifying and mitigating against potential nutrient loss. In the United States, farmer's adoption of NMPs has generally been coupled with a decrease in overall farm nutrient inputs (Shepard, 2005), resulting in some decreases in nutrient loss but often financial benefits (Genskow, 2012).

The presence of good grassland or crop covers, and crop residues, help to minimize nutrient and sediment losses by decreasing soil erosion, surface runoff, and nitrate leaching (Gabriel and Quemada, 2011). Constantin *et al.* (2010), for instance, showed that cover crops can decrease NO_3^--N leaching by approximately 36–62%. Variation, however, results from changes in soil type (Fullen *et al.*, 2006) and tillage management (Deasy *et al.*, 2010). Soils under arable crops are most susceptible to structural damage due to the frequency with which they are tilled (Regan *et al.*, 2012). Furthermore, arable soils can have higher P concentrations than grassland soils due to the more intensive use (e.g., planting, fertilization, and removal) of crops. Minimizing tillage, usually through shallow cultivation (i.e., <10 cm), helps to conserve soil

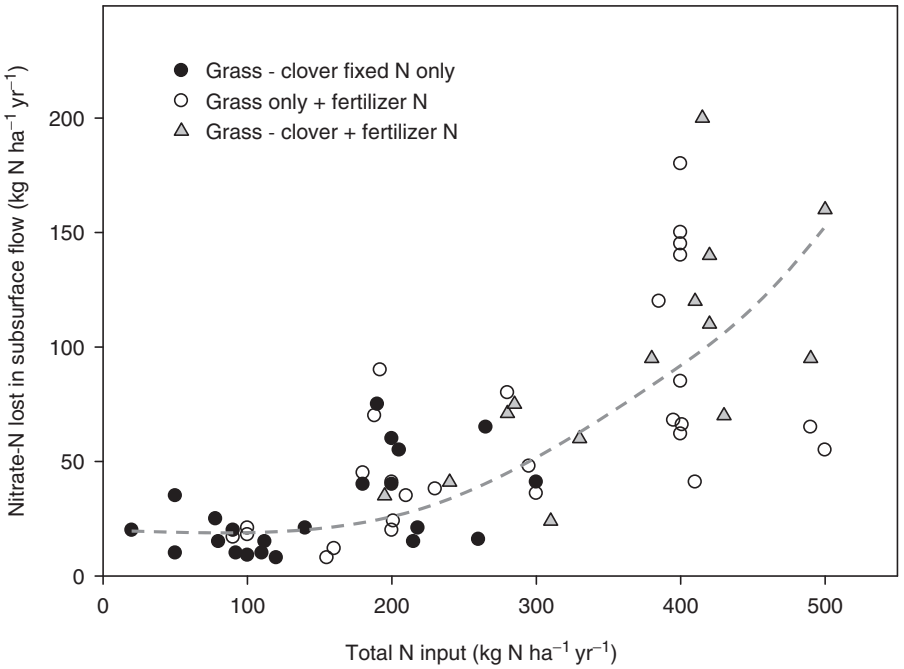

Figure 1 Nitrate-N lost in subsurface flow (leachate) from grazed grass – clover systems with and without N fertilizer and grazed grass systems with N fertilizer. Redrawn from Ledgard, S.F., 2001. Nitrogen cycling in low input legume-based agriculture, with emphasis on legume/grass pastures. Plant and Soil 228, 43–59.

carbon and promote aggregation, thereby reducing erosion and maintaining soil infiltration (Quinton *et al.*, 2010). Such techniques have been shown to decrease NO_3^--N and dissolved P losses by 49% and 17%, respectively (Kay *et al.*, 2009), and sediment loss by 78% (DeLaune and Sij, 2012). However, judiciously timed mechanical tillage and aeration can also decrease nutrient loss, particularly P, by facilitating greater redistribution of nutrients throughout the soil profile and increasing soil infiltration.

Fencing streams reduce streambank erosion and the direct deposition of excreta to streams by grazing animals (McDowell and Nash, 2012). In the Cannonsville Reservoir catchment, New York, fencing of streams decreased P loss by 32% (James *et al.*, 2007), whereas in New Zealand, a 90% reduction in total P concentrations was achieved once a headwater stream had been fenced off from red deer (McDowell *et al.*, 2008). Where fencing is impractical, provision of water troughs may help to reduce the time livestock spend near streams (Byers *et al.*, 2005).

At the field scale, surface runoff pathways may transport significant amounts of sediment and nutrient. Practices that intercept and slow flows, such as riparian zones, buffer strips, wetlands, and small reservoirs, encourage soil infiltration and sedimentation, thus decreasing sediment and nutrient loss. Wetlands have been shown to decrease NO_3^--N and P concentrations in surface runoff by 80% and 84%, respectively (Fisher and Acreman, 2004). However, large variation in removal efficiency is generally apparent (45–95% and 0–99% for N and P, respectively; Mitsch and Gosselink, 2007) in response to contaminant loading rate, hydraulic residency time, inflow concentrations, and substrate age (Fisher and Acreman, 2004). Riparian buffer strips, especially where trees are included, help to reduce light penetration, thereby limiting algal growth in streams (Hutchins, 2012). Vegetated buffer strips may decrease sediment and P loading by 9–97% (Bailey *et al.*, 2013) but can be easily circumvented and therefore ineffective if preferential or convergent flow paths operate (Verstraeten *et al.*, 2006).

Amendments added to soil and manures have also been used to decrease nutrient and sediment losses. Decreasing the solubility of P that would otherwise be available to surface and subsurface flow may be achieved through the application of aluminum sulfate to soils (McDowell and Houlbrooke, 2008; Smith *et al.*, 2001). Nitrification inhibitors (e.g., dicyandiamide (DCD)) are increasingly being used in grazing and cropping systems as a means to decrease NO_3-N leaching (Carneiro *et al.*, 2012; Di and Cameron, 2005; Monaghan *et al.*, 2009). DCD applied to grazed grassland in New Zealand was effective in decreasing N losses by 21–56% (Monaghan *et al.*, 2009). A similar decrease was reported (38–42%) following the application of cow urine to soil lysimeters (Dennis *et al.*, 2012). Nitrification inhibitors have also been applied in conjunction with the application of effluents. For instance, Corre and Zwart (1995) measured a 10% decrease in NO_3-N losses following DCD incorporation with a cattle slurry product. However, the effectiveness of DCD varies between soil types in response to drainage characteristics (Shepherd *et al.*, 2012) and soil temperature (Kelliher *et al.*, 2008). Recent detection of low-level residues of DCD found in New Zealand milk powder in 2012 has raised international consumer concern and is most likely to instigate international regulatory developments. Anionic

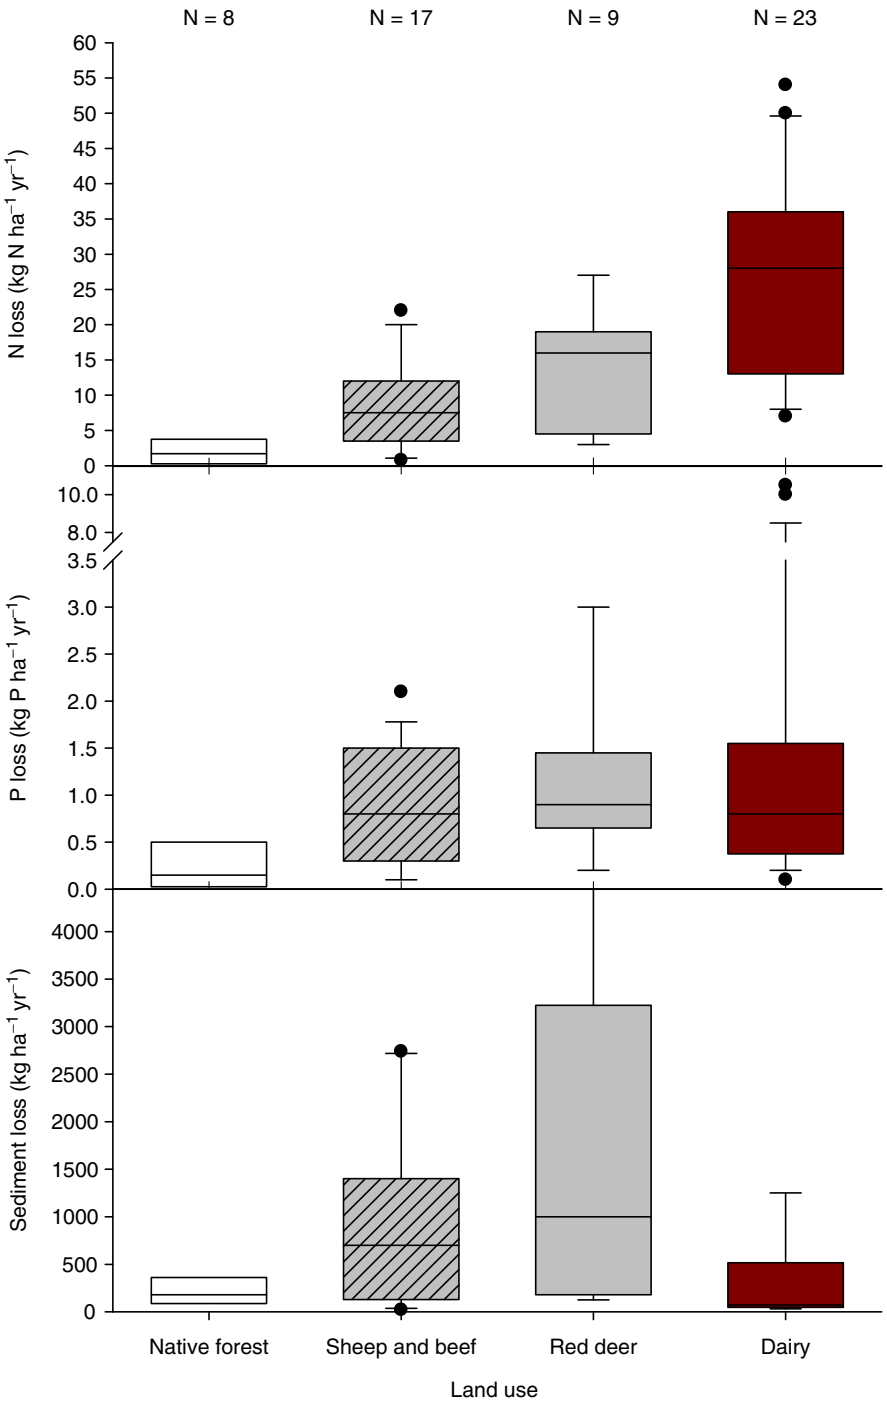

Figure 2 Nitrogen (N), phosphorus (P), and sediment annual loads for all catchment-scale studies conducted in New Zealand from 1975 to 2011 for different grazed grassland-based land uses compared with native forest with no agricultural development. Loads are shown as box plots showing the median and 25th and 75th percentiles (bottom and top parts of the box, respectively). The 10th and 90th percentiles are shown as whiskers and outliers. *N*=the number of studies in each stock class. Modified and updated from McDowell, R.W., Wilcock, R.J., 2008. Water quality and the effects of different pastoral animals. New Zealand Veterinary Journal 56, 289–296.

polyacrylamide has been applied to agricultural soils to control soil erosion by improving infiltration and aiding aggregate stabilization. Application has been reported to decrease sediment loss by 80–99% and improve infiltration by 15–50% (Sojka *et al.*, 2007).

As noted in the previous section, confinement of animals increases the emphasis placed on managing manures. Because the availability of manure N and P to loss in runoff declines exponentially with time since application, applying manure should be restricted to times of year when runoff is

unlikely (including snowmelt). Manure on grazed dairies can often be in the form of dilute slurry called farm dairy effluent (<1% solids). Poor land application strategies (i.e., when soils are wet) can often result in significant N and P losses that can be avoided by increasing storage capacity and applying effluent at a low rate (e.g., <4 mm h^{-1}) to dry soil. This enhances the interaction and uptake of nutrients by the soil, thereby decreasing their loss (Monaghan *et al.*, 2010).

Many of the mitigation strategies employed on cropping farms, and farms using animal confinement, are applicable to grazing operations as well. However, additional or modified strategies that encompass grazing management are required. For instance, reduced soil infiltration due to animal treading can lead to increased nutrient loss in surface runoff (Curran-Cournane *et al.*, 2011). Strategies such as restricting the grazing time of animals to 3–4 h (for maintenance feeding) when soils are wet have been demonstrated to limit soil damage and maintain infiltration, particularly during spring (Christensen *et al.*, 2012; Houlbrooke *et al.*, 2009; Piwowarczyk *et al.*, 2011). Drewry (2003), for instance, showed that the practice of grazing cows on wet soils resulted in significantly lower soil macroporosity (12.8% v v^{-1}) relative to a short 3-h grazing period (16.3% v v^{-1}) and full stock exclusion (21.6% v v^{-1}). Avoiding traffic on wet soils also applies to cropping systems whereby the use of farm machinery can be restricted or modified to maintain soil porosity and decrease nutrient and sediment loss via reduced axle loading, larger tyres, and minimizing tillage to increase soil-bearing strength (Chamen *et al.*, 2003; Prikner and Grečenko, 2007; Silgram *et al.*, 2010; Tullberg, 2010). Positioning obvious infiltration-excess areas, like farm tracks, lanes, and gateways, so that flow from these areas does not reach waterways also decreases contaminant losses to streams (Monaghan and Smith, 2012).

Single strategies that mitigate a component of nutrient and sediment loss can often be easily implemented. However, greatest mitigation efficiency is usually achieved when measures are implemented collectively and in the right place and at the right time. The concept of critical source areas (CSAs) that describes areas where contaminant sources coincide with transport mechanisms to isolate small areas of a field, farm, or catchment that account for the majority of nutrient and sediment loss is now widely recognized (Pionke *et al.*, 1997). Mitigation strategies that target CSAs tend to be more cost effective than measures that use blanket mitigation strategies across an entire area (McDowell and Srinivasan, 2009).

Legislation/Subsidies and Socioeconomic Instruments

Financial and technical support provided to farmers by taxpayers and consumers has declined in recent years. For instance, globally, financial contributions from government and industry comprised 37% of farm gate profits in 1986–88, whereas in 2008–10 the contribution was 20% (OECD, 2012). Despite this, the need for strategies to decrease pollution of water, particularly those aimed at curtailing diffuse nutrient inputs to waterways, has become paramount. A diverse range of strategies has been established to decrease the impact of agriculture on water quality and is implemented on local, catchment, national and international levels. However, it is increasingly recognized that these strategies are both affordable and cost effective so that policy and water quality objectives can be met without undue financial hardship or

land-use change (Shortle *et al.*, 2012). This is aided by a mix of economic incentives, environmental regulations, and information transfer to farmers.

Most Organisation for Economic Co-operation and Development (OECD) countries have overarching National Water Policies that are usually implemented at the state/regional level. National Water Policies, for example, Clean Water Act (US), Water Framework Directive (EU), and Resource Management Act (NZ), generally minimize point source pollution, even those from intensive livestock operations, via a permitting system that aims to meet quality guidelines (Wisen and Porter, 2006). Control of nonpoint pollution is generally regulated to a lesser degree and encouraged through provision of financial and technical assistance (Feather and Cooper, 1995). In the United States, a voluntary approach has delivered mixed results (Shortle *et al.*, 2012; Williams, 2002), whereas in the European Union production-based subsidies (e.g., Common Agricultural Policy) have often failed in controlling nonpoint source pollution (OECD, 2012). In New Zealand, a lack of government subsidies (i.e., an open market) causes a greater reliance on making 'the polluter pay' as opposed to 'pay the polluter.' However, a combination of technical assistance and compliance has shown promise in curtailing pollution from nonpoint sources (Caruso, 2000). For example, an agreement called the 'Dairying and Clean Streams Accord' was signed in 2003 by local and national government and the major dairy company Fonterra. The Accord is both a statement of intent and a framework for actions to promote sustainable dairy farming in New Zealand. One major performance target was the exclusion of dairy cattle from 90% of waterways by 2012 (Ministry of Agriculture and Forestry, 2009). This has, by and large, been achieved primarily due to voluntary leadership shown by industry. However, meeting effluent management objectives has continued to be a greater challenge with only 73% of farms meeting compliance standards. Although command and control policies internalize more costs within industry, high rates of noncompliance remain a challenge. Regarding voluntary efforts, barriers such as the economic cost to the farmer relative to the perceived gain, the lack of knowledge within the industry, or personal unwillingness and on-farm labor shortages mean collectively these voluntary approaches may fail. Financial incentives offered to farmers may better facilitate changes in farm practices to protect water quality. In most OECD countries, support (where given) is increasingly being tied to conditions to which the producer is obligated to fulfill (e.g., water quality targets). For instance, between 2008 and 2010, 30% of OECD subsidies were conditional on some type of contribution from the receiver, as opposed to 4% in 1986–88 (OECD, 2012).

Payments for ecosystem services schemes also incentivize environmental actions that protect water quality rather than control activities through legal obligation. By placing a value on the provision of environmental services that have a definable social benefit, a user (or beneficiary) pays approach can be established (Mayrand and Paquin, 2004). In the United States, for instance, the Conservation Reserve Program, operating since 1985, incentivizes farmers to retire environmentally sensitive farmland from production or avoid agricultural practices that impact on water and air quality and wildlife diversity. In return, government- or community-raised funds are paid to participating farmers. Such schemes implemented around the world have, by and large, been successful, although some issues over farmer financial flexibility have been raised (Landell-Mills and Porras, 2002; Mishra and Khanal, 2013). Common to all schemes enacting water quality targets is the need for informed scientific objectives as well as an overarching view of biophysical and socioeconomic drivers that cause nutrient and sediment loss.

Lag Times and Legacy Issues

One of the major challenges for those trying to improve water quality in agricultural catchments is the fact that despite remedial or mitigation actions, losses of N, P, and sediment may not decrease to desired levels that result in satisfactory water quality outcomes. Lag times often account for this phenomenon. Reasons for a long lag time include the following: (1) targeting the wrong contaminant causing water quality impairment, (2) changing hydrology (e.g., more frequent storm events), (3) incomplete or insufficient uptake and implementation of mitigation practices, (4) slow or tortuous transport pathways (e.g., nitrate via deep groundwater), (5) transformation and storage (e.g., deposition of particles and uptake of dissolved P), and (6) poor measurement or monitoring regimes. Many of these factors may also be defined as legacy issues, i.e., a hangover of past action of management.

An example of a legacy effect is the transport of nitrate via groundwater to the catchment outlet. The scientific and technical advisory committee of the Chesapeake Research Consortium (STAC, 2005) concluded that due to the varying age of groundwater within the catchment (1–50 years), and that much of the water flowing into the Bay was from groundwater, a scenario to manage N in the catchment would cause a 50% decrease in baseflow nitrate concentrations but would require 35 years lead-in time. Until then, nitrate in the streams and rivers of the Bay will reflect the legacy of past N losses from agriculture and may increase in line with more recent intensification before decreasing.

Legacy issues have also been noted when large storms deliver significant quantities of sediment into river networks. As a result, it can take a long time before storage and remobilization processes interact with stream beds, banks, and floodplains to clear this sediment out. Land-use change, such as deforestation, is a major cause of the sediment input into many rivers. For instance, conversion into agriculture in the late 1800s of the Coon Creek catchment in Wisconsin, part of the upper Mississippi, caused large losses of sediment to occur. In response, soil conservation measures were initiated, but it is only in the last few decades that these have begun to decrease sediment loads (Meade and Moody, 2010).

Although processes like sediment size sorting, dispersion, and flocculation can complicate the modeling and estimation of sediment time lags and legacy effects, the picture is more complicated for P, which, in addition to particulate forms, contains dissolved inorganic and organic fractions. Once enriched, soil test P can take a long time to decrease to a concentration that has little potential for P loss to runoff. By not applying P fertilizer, McCollum (1991) found that it took >17 years for Mehlich-1 extractable P concentrations within a fine

sandy loam in an arable system in the United States to decline from 99 g P m^{-3} to the agronomic optimum value of 20–25 g P m^{-3}. Similarly, Dodd *et al.* (2012a) estimated that it would take 23–44 years for 4 grazed grassland sites in New Zealand to reach a proposed environmental limit for water extractable P in surface runoff following cessation of fertilizer P inputs. Other strategies, such as the application of N fertilizer, may increase the rate at which P declines (Dodd *et al.*, 2012b). However, in the interim, sufficient P may have escaped to cause permanent damage in receiving water bodies (Bennett *et al.*, 2001).

Phosphorus in sediments can persist and dissolve into the water column long after P inputs have declined. This is a common problem associated with wastewater treatment plants that discharge into stream and rivers, enriching and saturating sediment with P and negating the capacity of the stream to buffer any additional P inputs (Ekka *et al.*, 2006). In deep stratified lakes the supply of P from bed sediment, termed internal loading, can persist for decades. In shallow lakes, P may be flushed within a decade (Hamilton, 2012). Perhaps of more concern is the fact that P enrichment has also been found in groundwater (Holman *et al.*, 2008), leading to the possibility that P concentrations may eventually be enriched in baseflow, viz., nitrate.

The influence of legacy issues and time lags must be taken into account if mitigation strategies are to prove effective. If not, they will confound efforts to meet water quality targets. However, Meals *et al.* (2010) outlined a number of steps that would aid in setting an achievable target despite a lag time. These include the follwing: good characterization of the catchment and contaminant transport processes (i.e., establishing a lag time), careful placement of monitoring stations to maximize the chance of seeing a mitigation effect, and design of an appropriate sampling regime (incorporating spatial replication) to ensure statistical significance of the target contaminant. Together with good communication, these should ensure that stakeholders and regulators reach a consensus on a target.

Conclusions

The challenge of decreasing the impact of agriculture on water quality is large and only projected to increase as either more land is brought into production or higher outputs are achieved from existing land. Many of the challenges are a function of geography whereby farming systems have arisen to feed local populations without consideration of climate or catchment conditions. These have led to local specialization that has resulted in regional water quality problems that have been exacerbated by poor management decisions. Much of the focus to improve water quality has been on the manipulation of current management systems or the incorporation of on-farm or catchment-scale mitigation technologies. Globally, there are many initiatives that aim to buffer the economic impact of changing management and strategies whose aim is to quickly decrease nutrient or sediment loss without regard for cost. Alternatively, there has also been greater focus on strategies to mitigate nutrient and sediment losses while improving profitability. Whichever approach is used, consideration of the time lags involved will be an important factor that communities must recognize if desired water quality outcomes are to be achieved.

Glossary

Agricultural meteorology The study of meteorological and micrometeorological conditions in agriculture.

Agrometeorological bulletin A report usually issued by the National Weather Services, describing current weather conditions and the evolution expected for the following week from the perspective of the agricultural management. An example is the Weekly Crop Bulletin published weekly by the US Department of Agriculture.

Climate outlook Often considered as a synonym of seasonal forecast.

Ensemble forecast A set of different forecasts all valid at the same forecast time usually obtained from running a forecast model many times starting from different initial conditions. This technique is used to quantify and convey uncertainties.

Probabilistic forecast Not to be confused with a probability forecast, it refers to the presentation of the outcome of ensemble predictions in probabilistic terms, usually a set of summary statistics.

Seasonal forecast A forecast with a lead time of 3–6 months.

Strategic decision problem An agronomic or agricultural problem referring to planning of agronomic relevant actions on time scales of a season, a year, or a few years.

Tactical decision problem An agronomic or agricultural problem that involves taking decisions on short time scales, usually of the order of days.

Introduction

Agricultural production and, more in general, the agricultural sector are highly sensitive to weather. Temperature, radiation, humidity, and wind conditions, along with water and nutrient availability, define the conditions for crop growth and yield formation. Weather further controls the emergence and spread of weeds, pests, and diseases and has a strong impact on animal health and performance (LeRoy Hahn, 1994). But weather is also important for the food chain as a whole. The storage of food and fodder can badly suffer from adverse weather conditions. Likewise the distribution of food and forage at local, regional, and global scale can be obstructed by the action of weather elements. As a result, prices of agricultural commodities are in many instances susceptible to variations in weather conditions (Shafer and Mjelde, 1994).

The establishment of agricultural practices reflects an evolving process in which optimal management strategies are identified with respect to what is perceived as normal climatic conditions. The occurrence of anomalous situations tend to move production systems away from the optimum, have negative effects on productivity, and prompt the implementation of protection plans. Knowledge of the forthcoming weather, even if imperfect, can markedly improve the preparedness and the capacity of farmers to cope with adverse conditions. Hence, possibilities to anticipate weather conditions have always been pursued by farmers and agricultural communities.

In earlier times, forecasting relied on the observation of natural phenomena, from which empirical rules could be inferred. A well-documented example is the practice of indigenous Andean communities to predict summer rainfall from changes in the apparent brightness of stars in the Pleiades during the spring (Orlove *et al.*, 2000). In this particular case, predictive capabilities are rooted in the fact that star visibility decreases in the presence of high-level clouds, which is often the case during El Niño years. Along the western slopes of the Peruvian Andes, the establishment of El Niño is indicative of reduced rainfall during the following growing season, a situation that eventually delivers the rationale for forecasting.

The availability of forecasts has dramatically improved in modern times, especially during the twentieth century with the establishment of the science of numerical weather prediction. The possibility to access weather forecasts at a wide range of spatial and temporal scales reflects the enormous advances that have taken place in the field since the first successful numerical integration experiments and the completion of the first operational numerical weather forecasts in the 1950s (Harper *et al.*, 2007; Lynch, 2008). Various aspects have contributed to these advances.

On the one hand, there have been impressive improvements in the quality of prediction systems, owing to a more realistic representation of the atmospheric and oceanic dynamics, the adoption of more refined numerical algorithms and parameterization schemes, advances in data acquisition and data assimilation, and the creation of multimodel ensemble forecasting systems (e.g., Palmer *et al.*, 2004). Such developments would not have been possible without an equally extraordinary increase in computational resources.

On the other hand, observational, technical, and scientific programs initiated by United Nations agencies, especially the World Meteorological Organization (WMO) along with the Intergovernmental Oceanographic Commission and the United Nations Environment Programme, were vital for establishing the global monitoring needed for a better understanding of climate variability at the seasonal scale. Ultimately, it is thanks to the Tropical Ocean Global Atmosphere program, a major component of the World Climate Research Program operated by the WMO, that the first successful predictions of El Niño by a prototype coupled ocean–atmosphere model system was delivered in the 1980s (Zebiak and Cane, 1987).

But weather forecasting has profited from decisions at the institutional level as well. An example is the establishment of

the European Centre for Medium-Range Weather Forecasts (ECMWF). With far-reaching implications is also the recent decision by the WMO to promote seasonal forecasting through the so-called WMO Global Producing Centres (GPCs) for Long-Range Forecasts. Currently, twelve weather forecasting services from all over the world are officially designated as WMO GPCs, including:

- The Bureau of Meteorology (BOM) (Australia)
- China Meteorological Administration (CMA)/Bejing Climate Center (BCC) (China)
- Climate Prediction Center (CPC), National Oceanic and Atmospheric Administration (NOAA) (United States of America)
- ECMWF (United Kingdom)
- Japan Meteorological Agency (JMA)/Tokyo Climate Centre (TCC) (Japan)
- Korea Meteorological Administration (KMA) (Korea)
- Meteo-France (France)
- Met Office (United Kingdom)
- Meteorological Service of Canada (MSC) (Canada)
- South African Weather Services (SAWS) (South Africa)
- Hydrometeorological Centre of Russia (Russia)
- Center for Weather Forecasts and Climate Studies/National Institute for Space Research (CPTEC/INPE) (Brazil)

Other major centers providing global seasonal forecasts are:

- The International Research Institute (IRI) for Climate and Society (United States of America)
- Asia-Pacific Economic Cooperation (APEC) Climate Center (APCC) (Republic of Korea)

Also worth mentioning in this context is the creation of consortia for promoting high-resolution limited area modeling, such as the Consortium for Small-Scale Modeling (COSMO) and High Resolution Limited Area Model (HIRLAM) consortium. There is little doubt that the possibility to run forecast models at spatial resolution of the order of 2–10 km opens new perspectives regarding the application of forecasts in agriculture.

Traditionally, the dissemination of weather forecasts has taken place at a national or regional level. Forecasts issued by the national weather services are distributed through various channels, including newspapers, radio and television, and, more recently, the Internet and mobile telephones. Nonetheless, in many areas of the word access to forecasts remains limited. This is especially the case concerning the access to seasonal forecasts and climate predictions in developing countries. Adoption of seasonal forecasts has suffered not only from inadequate distribution but also from the lack of interaction between providers and users. The creation of the so-called Regional Climate Outlook Forums (RCOFs) starting in the 1990s has considerably improved on this situation.

Types of Forecasts, Forecast Characteristics, and Formats

There are two basic kinds of forecasts that are potentially of use for agriculture: public forecasts, on the one hand, and more specialized forecasts, advisories, and other products, on the other hand (Flynn, 1994; Das *et al.*, 2012). Traditionally, both types of forecasts have been issued by national weather and agrometeorological services. However, in recent years an increasing number of private companies have appeared on stage, offering a portfolio of products that is of great interest for farmers and consultants.

General-purpose forecasts can be classified according to the time span embraced by the prediction. In broad terms the following categories can be identified:

- Nowcasts: Forecasts with a lead time of between 1 and 6 h issued for a limited geographic area at high spatial resolution through consideration of persistence and evolution of patterns identified on satellite or radar imageries and the analysis of local observations. Owing to their very short lead time, nowcasts are most valuable for early warning.
- Very short-range forecasts: Predictions of the local weather for up to 12 h that are concerned with the evolution of smaller scale, short-lived, often intense weather phenomena, such as tornadoes, hail storms, and flash floods. Very short-range forecasts are issued at high spatial resolution using a variety of techniques, including extrapolation of trajectories and the interpretation of model-based, limited area forecasts.
- Short-range forecasts: Predictions of the evolution and movement of large- and medium-sized weather systems with lead times of 12–72 h.
- Medium-range weather forecasts: Deterministic or probabilistic (ensemble) predictions referring to the evolution of synoptic weather patterns out to 7–10 days, obtained from the integration of numerical models of the atmospheric circulation.
- Monthly or extended forecasts: Monthly or extended forecasts usually refer to predictions with a lead time longer than the 10 days achievable with medium-range forecasts but not exceeding the monthly scale. These forecasts are issued at the global scale and with moderate spatial resolution.
- Long-range or seasonal forecasts: Probabilistic forecasts at the global scale extending out to 3–6 months. As with monthly forecasts, seasonal forecasts are produced by an integrated forecasting systems built around a coupled ocean–atmosphere model. Because variability at these time scales can be considered as a fundamental aspect of climate, the expression 'climate outlook' is often used as a synonym of 'seasonal forecast.'

Depending on lead time, forecasts are either deterministic or probabilistic. Deterministic forecasts are obtained from a single integration of the differential equations that describe the dynamics of the atmosphere and are appropriate for predicting weather a few days ahead. Beyond approximately 1 week, the evolution of the state of the atmosphere becomes unpredictable in a deterministic sense. Reasons for this are the chaotic nature of the atmosphere and the sensitive dependence of its dynamics to initial conditions (Lorenz, 1993). Therefore, rather than considering a single evolutionary path, forecasts with lead times exceeding the week are issued by running atmosphere (or coupled ocean–atmosphere) models several times with slightly varying initial conditions.

Increasing lead time is usually associated with decreasing quality of the forecasts (Das *et al.*, 2012). In the case of monthly and seasonal forecasts, forecast quality is higher for temperature than for precipitation and higher in regions where the local effects of the El Niño-Southern Oscillation (ENSO) are strongest. According to Murphy (1997), quality should be defined with reference to the totality of the statistical characteristics of the forecasts, the verifying observations, and their joint distribution. Specific aspects of quality can then be recovered from the conditional and marginal distributions associated with the factorization of the joint distribution. Accuracy and skill are often considered in verification studies. The former refers to the average degree of correspondence between individual forecasts and observations and is typically quantified in terms of the mean square error or the mean absolute error. The latter is a relative measure of accuracy that compares the accuracy of the actual forecast with the accuracy of a naïve forecasting system based, for example, on climatology or persistence.

Monthly and seasonal ensemble forecasts of temperature and precipitation are usually presented in a probabilistic format. Very common is the adoption of three equiprobable categories to represent below-normal, normal, and above-normal conditions. Graphically, forecasts are often provided as probabilities for each category or, as in the case of the climate outlooks prepared and disseminated by the IRI for Climate and Society, as probabilities of the most likely category.

As opposed to public forecasts, specialized forecasts and agrometeorological advisories are issued for crop growers and livestock producers. Besides predictions for relevant weather elements (maximum and minimum temperature, precipitation probability and expected rainfall amounts, sunshine duration, cloud cover or radiation, air humidity, dew, and wind), they usually deliver farm management information and early warnings (Flynn, 1994). Farming aspects include the handling of crop production (planting, harvesting, postharvest processing, measures to abate the risk of frost or heat stress, irrigation, and fertilization); the control of weeds, pests, and diseases (spraying operations); and the management of animal production (environmental requirements, nutritional needs, and health).

Agrometeorological advisories are issued for the local or regional scale. The common practice is to provide forecasts for the following 5 days, which represents a minimum time lapse for implementing preventive measures and capitalizing the benefits of favorable periods. The preparation of advisories is usually carried out by trained agricultural meteorologists at national weather services in consultation with a panel of experts in agricultural and animal sciences, viz., agronomists, soil scientists, entomologists, horticulturists, plant breeders, cattle farmers, and plant and animal pathologists (Das *et al.*, 2012).

In addition to public forecasts and agrometeorological advisories, other types of products can provide useful information to growers, consultants, and authorities. In view of the enormous implications that drought has on agricultural production and food security, drought bulletins play a key role for agricultural risk management (Sivakumar *et al.*, 2005; Sivakumar and Motha, 2007). Drought bulletins are available from the National Weather Services, specialized Drought Monitoring Centers, and other public institutions. Examples are:

- The Australian BOM, which releases the Rainfall Deficiencies and Drought Information).
- The US CPC maintained by the National Center for Environmental Predictions as part of the NOAA, which publishes a Drought Monitoring that relies on the Palmer Drought Severity Index (PDSI) and Crop Moisture Index (CMI).
- The US Drought Mitigation Center associated to the University of Nebraska, which issues the US Drought Monitor;
- The Drought Early Warnings available from the Climate Services Centre run by the Southern African Development Community (SADC).
- The Intergovernmental Authority on Development (IGAD) Climate Prediction and Applications Centre (ICPAC) with seat in Nairobi, which is responsible for the dissemination of the Africa Drought Monitor.
- The International Water Management Institute (IWMI), which issues the Southwest Asia Drought Monitor.

Agricultural Decision Problems and Forecasting Applications

There are a variety of agricultural decisions that benefit from weather forecasts (e.g., Wilks, 1997; Meza *et al.*, 2008; and Das *et al.*, 2012) and it has become customary to distinguish between tactical and strategic applications (Stepanski *et al.*, 2012).

Tactical applications refer to short-term decisions that are concerned with field operations on time scales ranging from a few hours to up to a few days. Examples of tactical decision problems are the following:

- Field preparation – This is a preseason activity that aims at providing optimal conditions for sowing, seed germination, and the early stages of growth. Field preparation thus addresses soil water and nutrient availability. Elimination of weeds is also part of the preseason program. In dryland farming, the goal is often to achieve an optimum soil water profile. Consideration of soil moisture is also a key element in relation to trafficability. Therefore, precipitation forecasts play a major role at this stage, but forecasts for temperature and radiation are important in connection to workability. To be effective, preseason forecasts should have a validity period of not less than a week (Das *et al.*, 2012).
- Sowing/planting – Soil temperature, soil moisture, and radiation are all important elements in relation to seed germination and the establishment of the crop. Specific requirements vary across crops and varieties and depend on soil characteristics. Frost occurrence around sowing can adversely affect seedling development and low temperatures can increase the bolting risk. However, alternating temperatures assist the germination of many species of seeds and frost during presowing can improve soil quality. For rainfed agriculture in the seasonally arid tropics, the decision of sowing is connected to the onset of the rains. Rules to determine the optimum time for sowing are

generally formulated with respect to amount and duration of the first rains and the risk of a potentially false start in the absence of significant rain after sowing (Stern *et al.*, 1982; Sivakumar, 1988). Thus, short-range forecasts of temperature are usually appropriate at the sowing time, whereas in rainfed agriculture the decision of sowing benefits most from medium-range precipitation forecasts.

- Irrigation – When the natural availability of water and nutrients limits crop development, irrigation and the application of mineral or organic fertilizers are essential to sustain growth and obtain adequate yields at harvest. The economic problem is often one of minimizing at the same time crop damages and costs. In practice, irrigation is scheduled taking into account the crop water requirements. Standard procedures for assessing crop water requirements have been developed by the Food and Agriculture Organization of the United Nations starting in the 1970s, with a major update in the 1990s related to the adoption of the Penman–Monteith equation as a basis for computing the reference evapotranspiration (Allen *et al.*, 1998). Data for daily minimum and maximum temperature, solar radiation, air humidity, and wind are required on input to the latter; accordingly, forecasts for the same variables are needed to support this specific decision problem. In addition, day-to-day precipitation forecasts can be used to avoid unnecessary irrigation and limit the environmental problems associated with fertilizer and pesticide leaching (Wilks, 1997).
- Fertilization – As nutrient access through the roots is controlled by the dilution process at the surface and the movement of the solutes through the soil, scheduling of fertilization primarily relies on short-term precipitation forecasts.
- Harvesting – In cereal and forage production, the basis for scheduling harvest operations is a consideration of grain or hay quality at harvest and drying requirements for post-harvest processing. Because of the risk of mold formation, too high a moisture content makes crop products unsuitable for storage. But too low a moisture content is also undesirable because it reduces the profits. Premature harvests have thus negative impacts on grain quality, as have delayed harvests in persisting cool wet weather conditions (Hayward, 1987). Early harvest may often be the preferred option, even though there is a risk of incurring in extra costs for artificial drying. Clearly, both short-term and medium-range forecasts are needed for a successful planning of harvest operations.
- Frost protection – In orchards, frost protection is necessary when air temperatures fall below the freezing point in nights characterized by clear-sky conditions and radiative cooling. This is often the case in hilly or mountainous regions, where cold air tends to pile up in the valleys, and in the humid subtropics. When and where active or passive measures of frost protection can be put in place, this is usually done on the basis of forecasts for minimum temperature. Traditional approaches to forecasting minimum night temperatures rely on extrapolating weather data for the past day by empirical methods (Georg, 1978). More accurate predictions can be obtained from simulations with physically based models (e.g., Lhomme and Guilioni, 2004) or more advanced statistical techniques (e.g., Ghielmi and Eccel, 2006). In many areas of the world, the availability of short-range, limited area forecasts at very high spatial resolution provides further support for frost protection activities.
- Management of pests – Insects are an important class of pests and affect crop production and orchards alike. At the global level, climate is the dominant factor determining the abundance and distribution of harmful insects. Insects are cold blooded; development rates and number of generations per season are determined by temperature (Logan *et al.*, 2006). Excessive temperatures, however, reduce insect longevity and increase mortality. Wind conditions are important in relation to insect migration, suggesting that some aspects of insect control may profit not only from short-range temperature forecasts but also from a broader palette of forecasts products.
- Foliar application of agricultural chemicals – The treatment of crops and trees with chemicals, such as herbicides, insecticides and fungicides, growth regulators, and hormones, can be necessary to prevent damages from pests and diseases and support the development of crops. Forecasts are needed not only to schedule and guide the application of such products but also to avoid unwanted environmental pollution. An accurate evaluation of time schedule and applied amounts is often of economic relevance, because the costs of chemicals can easily become very high. Timely forecasts of air temperature and humidity can be translated into forecasts of leaf temperature and wetness, which are the critical elements for guiding the application of chemicals. Depending on the application technology, knowledge of the expected wind conditions is also of great importance, with emphasis on possible changes in speed and direction during the time of the application. As precipitation can dilute and wash off the chemicals, the decision of whether and how to apply chemicals can further profit from short-term precipitation forecasts.
- Transport of agricultural products and animals – In market-oriented agriculture, products are usually transported over long distances. Conditions during transport must be such as to prevent deterioration of the products. Temperature has a strong impact on product quality, and therefore temperature forecasts are decisive for planning transport, especially when substantial temperature variations are expected along the transport routes. In relation to the carriage of living animals, weather is even more decisive, because it has a direct impact on animal health. Finally, severe weather conditions can disrupt transportation itineraries. Hence, forecasts of storms, floods, and the like are vital in regions frequently exposed to weather hazards.
- Forage production – Although hay making can be considered by the same tokens as crop production, in grazing systems the objective is to maintain equilibrium between herbage demand and supply. Hence, the decision problem is primarily the one of a judicious choice of feeding patterns. This requires monitoring sward conditions and adjusting stocking densities. Weather forecasts should, therefore, be aligned with both aspects. Considerations of forage quality are equally important, because they can have profound implications for animal health (Hugh-Jones, 1994).

- Forage preservation – The traditional approach to forage preservation is by drying the harvested biomass in the field during one or more days. Rain occurring during this time can damage the forage and extend the drying period. In the latter situation, the forage may become exposed to further damage from later rains. In areas where the skill of rain forecasts out to 5 days is sufficiently high, hay-making reliability can markedly profit from short-range forecasts (Dyer and Baier, 1981).
- Livestock management – As with crops production, animal production is exposed directly and indirectly to variations in weather conditions. Aspects of animal farming that require the attention of farmers are nutrition, performance and production, reproduction, and health. Direct effects of weather are those that influence in first place the thermal regime of animals. Accordingly, weather elements that need to be monitored and forecasted are dry-bulb temperature, air humidity, solar radiation, and wind. Indirect effects of the atmospheric environment on animals are those relative to forage production and the outbreak of diseases.
- Diseases in animal production – A variety of viral, bacterial, and parasitic diseases can harm animal health and cause severe setbacks in animal production. Economic losses can be particularly severe in the tail of epidemic outbreaks. In tropical regions, there is a considerable interest in vectorborne diseases that are mediated by hot-weather insects, such as mosquitoes, midges, mites, flies, and others. As mentioned by Hugh-Jones (1994) various forms of livestock parasitism and diseases can be forecasted using weather data. An example is congenital hypocuprosis of sheep, which can be forecasted from the number of days with snow cover. From an epidemiological perspective, forecast applications should primarily address prevention and intervention programs. Successful applications have been documented, for example, in relation to the outbreak of foot-and-mouth disease in northern countries (Hugh-Jones, 1994), an airborne disease whose progress in mid-latitudes and high latitudes is mostly related to weather.

As opposed to tactical applications, strategic applications are concerned with decision problems on time scales ranging from the intraseasonal to the multiannual and with spatial scales exceeding the regional. There are a number of atmospheric circulation phenomena that are responsible for seasonal to interannual fluctuations in temperature and rainfall, including the Madden–Julian Oscillation (Madden and Julian, 1972), the ENSO (Philander, 1990), and the North Atlantic Oscillation (Hurrell *et al.*, 2003). The first is largely responsible for intraseasonal variability in the tropical atmosphere. The second is a phenomenon of coherent variations in sea surface temperatures, atmospheric pressure, and atmospheric convection with a characteristic time scale of a few years that has its roots in the equatorial Pacific Ocean but whose implications for precipitation are felt at the global scale. The third is a swing in the atmospheric sea-level pressure difference between the Arctic and the subtropical Atlantic associated with changes in seasonal mean heat and moisture transport across the Atlantic that has significant impacts on terrestrial, agricultural, and marine ecosystems.

Strategic decision problems are encountered in a wide spectrum of agricultural activities (Meinke and Stones, 2005):

- Intraseasonal decisions – These include decisions concerned with logistics (for instance, scheduling of planting and harvest operations) and crop management (for instance, fertilizer application and the use of pesticides). Time scales involved extend from 2 to 6 months.
- Seasonal decisions – Choice of crop type and herd management. Time scales involved are of between 6 months and 1 year.
- Seasonal to interannual decisions – Choice of crop sequences and stocking rates. Time scales involved are of between 6 months and 1 year.
- Annual to interannual decisions – For instance, decisions in relation to crop rotations. Time scales involved are of between 1 and 2 years.

In market-oriented agriculture, insurance solutions to hedge weather risks and associated economic losses represent one of the many options available for risk management. Complementing traditional insurance instruments, such as hail insurances, weather derivatives, and index-based weather contracts, have gained in attractiveness in recent years (Jewson and Brix, 2005). In many situations, hedging weather with derivatives or indexed-based products represents a perfect complement to weather forecasts. On the one hand, weather derivatives can, namely, support forecast-based decisions by covering the costs of taking action and by hedging the possibility that a forecast is wrong. On the other hand, weather forecasts play an important role for the valuation of weather derivatives, because the availability of forecasts reduces the range of outcomes that needs to be covered by the insurance. Regarding cropping systems, contracts usually extend over the growing season. In this case, combination of medium-range forecasts and seasonal predictions is often the preferred option, in spite of the challenge to merge the two types of forecasts.

Operational Aspects

Successful application of weather forecasts and climate outlooks to agricultural decision problems are conditional on matching the specific requirements of each application. Relative to crop production and animal farming, information is usually needed at the local and daily scale. Knowledge of temperature and precipitation is at times sufficient to resolve management questions, but in many cases predictions for a more specific set of variables are needed.

These requirements are basically satisfied by short-term forecasts obtained from nesting limited area models into regional and global models. This strategy, also denoted as dynamical downscaling, requires substantial computing resources and has gained relevance in the operational context only during the recent decades. Examples of operational high-resolution systems are COSMO, a European enterprise with partners from Germany, Switzerland, Italy, Greece, Poland, and Romania , and HIRLAM, a European initiative as well, with partners from Denmark, Estonia, Finland, Iceland, Ireland, the Netherlands, Norway, Spain, and Sweden.

The handling of operational seasonal forecasts, however, is less straightforward for at least four reasons:

- first, their coarse spatial resolution, which is typically of the order of a few degrees longitude and latitude;
- second, the need to correct for systematic errors in the predicted fields, which arise from increasing model drifts as the integration is carried forward (Stockdale, 1997);
- third, the need to recover daily values from the average statistics used for the dissemination of the forecasts;
- and fourth, the need to retrieve information not directly available from the forecasts.

Enhancing spatial resolution and bias correction are often tackled with the help of the so-called statistical or empirical spatial downscaling (Wilby and Wigley, 1997; Wilks, 2011). To be precise, statistical downscaling refers to a full array of techniques that comprises among others analog techniques, multiple linear regression, singular value decomposition analysis, canonical correlation analysis, the application of empirical orthogonal functions, and nonlinear statistical methods, such as artificial neural networks. Irrespective of the specific procedure adopted in practice, at the core of statistical downscaling is the development of transfer functions for mapping large-scale predictors (a set of explanatory variables) onto different realization of the local weather.

The simplest option for bias correction is to calibrate the forecast using additive or multiplicative shifts. The former are suitable for temperature, the latter for precipitation. For temperature, this solution provides in general satisfactory results because temperature biases are for the most part caused by an improper representation of the earth's orography in weather forecast models. For precipitation, applying multiplicative shifts to forecasted daily precipitation often provides only limited benefits because atmospheric models are known to systematically overestimate the frequency of rainfall events, especially in the extratropics (e.g., Frei *et al.*, 2003). Systematic errors in predicting the succession of wet and dry spells can have serious consequences for assessing crop water requirement or for scheduling fertilizer or chemical applications. This calls for correction strategies that are able to recover both the persistence of wet and dry spells and the transition probabilities between wet and dry spells, which is not the case for standard bias correction algorithms (Ines and Hansen, 2006; Schmidli *et al.*, 2006).

A more sensible alternative is to generate synthetic daily weather conditioned on the forecasts (Hansen *et al.*, 2006). Weather generators of either the Richardson type (Richardson, 1981) or the serial type (Racsko *et al.*, 1991) have been around since the 1980s. Nowadays they are often integrated into crop models and decision support systems and are increasingly used in forecast applications, not seldom in combination with statistical downscaling (Feddersen and Andersen, 2005). Stochastic weather generators are computationally inexpensive, making it possible to simulate weather sequences of basically unlimited length, out of which subsamples with the desired statistical properties can be taken (Calanca *et al.*, 2011).

Once the postprocessing of the forecasts is completed, the content of the forecasts can be passed to specialized models that translate the information into operational terms. Well known are crop simulation models (Alexandrov, 2002), but process-based or empirical models exist for a full range of agricultural activities, including models for the management of water resources, for forecasting frost occurrence, for the control of pests and diseases, for predicting grain quality of cereals, for predicting the moisture content in hay, for the control of storage facilities, and the like.

Many of these models came into life as specialized tools for a narrow field of applications. However, recognizing the need for integrated approaches, efforts have been undertaken to assimilate sectorial models into comprehensive decision support systems (Weiss, 1994). Examples of sophisticated modeling environments that can address multiple tasks are:

- The Agricultural Production Systems sIMulator (APSIM) (Keating *et al.*, 2003), a highly advanced simulator of agricultural systems that can address a range of plant, animal, soil, climate, and management interactions. APSIM has been used for the assessment of the value of seasonal climate forecasting and in a broad range of other applications (support for on-farm decision making, farming systems design for production or resource management, analysis of supply chain issues in agribusiness, development of waste management guidelines, risk assessment for policy making, and as a guide for research and educational activities).
- CropSyst (Stöckle *et al.*, 2003), a multiyear multicrop simulation model developed as an analytic tool to study the effects of management on the productivity of cropping system and their environmental implications, including soil erosion. Apart from the crop simulation component, the CropSyst suite provides access to the following: ClimGen, a climate generator based on WGen; Arc/Info – CropSyst Cooperator, a utility for running simulation models over Arc/INFO GIS map coverages; CANMS, the Comprehensive Animal Nutrient Management System for the simulation of on-farm production of animal fodder; and the Rural watershed model, a component for erosion and a runoff simulation at the regional scale.
- The Decision Support System for Agrotechnology Transfer (DSSAT) (Jones *et al.*, 2003; Hoogenboom *et al.*, 2012). DSSAT is a software application program that comprises crop simulation models for more than 28 crops and is supported by database management programs for soil, weather and crop management as well as experimental data. DSSAT has been used for many applications ranging from on-farm and precision management to regional assessments of the impact of climate variability. The target user group is wide, embracing researchers, educators, consultants, extension agents, growers, and policy and decision makers.
- A model for Epidemics Prediction and Prevention (EPIPRE) (Zadoks, 1981, 1984). It is one of the whole family of models that can be used for guiding the application of chemicals in response to the appearance of pests, diseases, and weeds in cropping system and orchards. EPIPRE is a well-documented example of a decision support system that has effectively been operated by the producers (Weiss, 1994).
- The Gossypium Simulator/Cotton Management Expert system (GOSSYM/COMAX). Initially developed in the

wake of the economic competition for synthetic fibers in the 1980s (Lemmon, 1986). Its crop component, GOSSYM (Baker *et al.*, 1983), is one of many models available for simulating the growth of cotton (genus *Gossypium*). GOSSYM is a comprehensive software that has widely been used in commercial agriculture to aid in making crop management decisions (McCauley, 1999), especially in the Southeastern United States, where a network of automated weather stations has been run by producers to collect the necessary input data. Recently, GOSSYM has been coupled to the Climate extension of the Weather Research and Forecasting model (CWRF) (Liang *et al.*, 2012). This integration makes it possible to run GOSSYM in a spatially distributed setup.

Economic Value of Weather Forecasts

Many investigations conducted in the past have shown that real economic benefits can be obtained from the adoption of weather forecasts. Surveys of case studies can be found in Omar (1980), Mjelde *et al.* (1989), Johnson and Holt (1997), Wilks (1997), Hill and Mjelde (2002), Meza *et al.* (2008), and on Richard Katz's web page. In *ex ante* assessments, the potential benefits are valuated before the forecasts are actually adopted by the end users. In contrast, *ex post* assessments seek for outcomes following adoption. In both cases, the focus is on the benefits for individual actors, but examples are also available that address the economic benefits at the market level.

Another distinction often considered in assessments of the economic value of weather information is the one between descriptive studies (e.g., Stewart, 1997), in which the decision process is analyzed in the light of actual user responses, and prescriptive studies (e.g., Wilks, 1997), in which the decision process is analyzed within the framework of a normative theory. In practice, prescriptive studies seek to identify optimal solutions by looking at how forecasts should be used in theory, often assuming that the decision makers act to maximize monetary returns. Although assumptions are, as a rule, idealized, the results can sometimes be used to formulate explicit recommendations. This can help improving decisions made by users who face the uncertainties regarding future weather conditions.

The rationale for the economic valuation of weather forecasts has often been explained with the help of so-called static cost/loss models (Richardson, 2012). These are prototype models in which the decision maker can only choose between two possible actions ('protect' against 'do not protect') and future events are limited to the occurrence, or not, of adverse weather conditions. Taking protective action always generates costs, whereas losses have to be assumed if protective action is not taken in spite of adverse weather. Given a probability of adverse weather conditions from climatological data, the optimal decision is to protect if this probability exceeds the ratio between costs and losses (whence the name), and not to protect otherwise.

As pointed out by Katz and Murphy (1997a), the possibilities to apply static cost/loss models to real situations are limited because:

- Forecasts are usually far from perfect, which requires introducing a measure of the forecast quality (Murphy, 1997). It can be shown that in this case there exists a quality threshold below which the additional information provided by the forecast has no value, no matter its content.
- Decision-making problems are dynamic, rather than static. This means that current decisions influence future actions. An orchardist, for instance, must decide in spring whether to protect or not, because this is the season when the buds are potentially exposed to damage from freezing temperatures. But because buds that are damaged or killed cannot recover and decisions taken in spring affect the rest of the season, the problem has clearly a dynamic component.
- Price levels cannot be assumed as constant, and in practice discount rates need to be taken into account.
- Successive realization of the weather are only ideally independent from one other, because most weather variables do show a tendency for persistence on time scales that may differ from variable to variable.

Access to Long-Range Forecasts in Developing Countries

Developing countries are most vulnerable to climate variability at the seasonal scale. In tropical countries, where food production still relies on rainfed cropping systems, changes in seasonal rainfall patterns can threaten the livelihood and the survival of entire communities and societies. The occurrence of a record-breaking El Niño event at the end of 1997, with its impacts on the global scale, helped raising the awareness of the public opinion concerning the societal implications of climate variability at the seasonal scale. Because operational El Niño forecasts were already available at that time, it also fostered the belief that long-range forecasts can significantly contribute to cope with negative impacts of weather vagaries.

The adoption of forecasts by farmers and rural communities, stakeholders, advisory and agricultural extension services, as well as authorities, is facilitated if the forecasts are tailored to meet the information requirements by the various end-user groups. It was at a Workshop on Reducing Climate-Related Vulnerability in Southern Africa (Victoria Falls, Zimbabwe, October 1996) that the idea of creating consensus forecasts for the benefits of society through the interaction of different actors was first discussed. That workshop marks the birth of the RCOFs (Ogallo *et al.*, 2008). Socioeconomic sectors addressed by RCOFs are numerous, including public health, energy production, and disaster risk prevention. Still, agriculture, food security, and the management of water resources have received special attention.

The RCOF process is strongly supported by the WMO and has profited much from efforts undertaken by the WMO to establish the GPCs for Long-Range Forecasts. RCOFs are primarily participatory initiatives at the regional scale that seek to deliver relevant information through the involvement of National Weather Services, regional climate institutions, and other local partners. The development of targeted seasonal forecasts in the context of RCOFs involves several steps (Ogallo *et al.*, 2008):

- determining the critical seasons for the various socioeconomic sectors and establishing a timetable for the delivery of forecasts;

- convening the expert team, including meteorologist and stakeholder representatives;
- reviewing current climate conditions and forecasts for the season ahead;
- reviewing the possible impacts of current and future conditions on human activities within the region of interest and formulating response strategies;
- producing consensus forecasts that will be applied and fine-tuned by the national weather services;
- developing strategies for a timely delivery of the consensus forecasts;
- accompanying the process of the adoption of the consensus forecasts, evaluating their practical outcomes.

Aside from issuing consensus forecasts, RCOFs have also taken a leading role in capacity building, offering training sessions for regional meteorologists. In addition, RCOFs have offered a platform for reviewing impediments to the use of information, discussing reasons for lack of reliability in the delivered information, and evaluating strategies for new developments.

The level of acceptance of the consensus forecasts, and the RCOFs as a process, has not always been high. In a review of first experiences in Southern Africa, Patt *et al.* (2007) identified several critical issues. For instance, restrictions on credits by the banks and an overly cautionary attitude by the farmers were observed in Zimbabwe in response to likely dry conditions that were forecasted in relation to the 1997 El Niño episode. This led to frustration when people realized later in the season that rain amounts would actually come close to normal. Similarly, the decision to delay the humanitarian programs for several million people facing a food crisis in Ethiopia and neighboring countries during 2000 can be explained by the skepticism in the forecast issued in 1999 for drier-than-normal conditions during the spring of 2000 in the Greater Horn of Africa.

Nonetheless, in many cases the adoption of forecasts from RCOFs has been seen in a positive light (Patt *et al.*, 2007). For instance, in Mali and Zimbabwe farmers benefitted from receiving timely forecasts along with support from local extension services. Successful stories have also been reported from other continents. This is the case for Western South America (Martínez Güingla and Mascarenhas, 2009), where considerable efforts have been undertaken to develop community information systems with the support of mobile telephone companies and to translate climate bulletins in native languages. As a result, by 2009 long-range forecasts distributed via the Internet, e-mails, radio, and mobile telephones were available to more than 60% of the potential users, and this number has been steadily increasing ever since.

To sum up, the success or failure of RCOFs has been a matter of fulfilling, or not, three basic conditions:

- Availability of personalized forecasts. Although communicating forecast uncertainties by adopting a probabilistic framework is important (Ogallo *et al.*, 2008), experiences gained from the African RCOFs have clearly indicated that there is scope to provide guidance to the interpretation of probabilistic seasonal forecasts (cf. also Wilks, 2000).
- Commitment at the institutional level. The development of consensus forecasts that do effectively meet the end-user needs has been possible whenever user groups and organizations have taken an active role in the RCOFs. But when participation in planning the agendas and in forecasting activities has been little, forecasts have remained at a very general level.
- Implementation of capacity building and training programs.

Although the RCOFs were pioneered in Africa, their expansion to other areas of the world has been rapid. Currently, the following RCOFs are in operation:

- The Greater Horn of Africa COF (GHACOF), which covers the countries Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Rwanda, the Sudan, Somalia, Tanzania, and Uganda and is being coordinated by the Intergovernmental Authority on Development (IGAD) Climate Prediction and Application Center (ICPAC), Nairobi, Kenya.
- The Southern Africa COF (SARCOF) coordinated by the SADC Drought Monitoring Centre (SADC-DMC), Gaborone, Botswana and covering the fourteen countries comprising the SADC Member States, namely, Angola, Botswana, the Democratic Republic of Congo, Lesotho, Malawi, Mauritius, Mozambique, Namibia, Seychelles, South Africa, Swaziland, Tanzania, Zambia, and Zimbabwe.
- Prévision Saisonnière en Afrique de l'Ouest (PRESAO), the West Africa COF coordinated by the African Centre of Meteorological Application for Development (ACMAD), Niamey, Niger.
- The Southeast of South America COF (SSACOF) with participation from Argentina, Brazil, Paraguay, and Uruguay. As opposed to other RCOFs, SSACOF is coordinated by each of the participant countries by rotation, and the latest seasonal outlook and related products may be obtained from the web sites of the respective National Weather Services.
- The Western Coast of South America COF (WCSACOF) coordinated by Centro Internacional para la Investigación del Fenómeno de El Niño (CIIFEN, International Research Centre on El Niño), Guayaquil, Ecuador, with participation of Bolivia, Chile, Colombia, Ecuador, Perú, and Venezuela.
- Foro Regional del Clima de América Central (FCCA) the COF for Central America, which sees the participation of Belize, Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica, and Panamá.
- CARICOF, the COF for the Caribbean area established in 2012 after closure of the CCOF (Caribbean FOC). Participating countries are Antigua, Bahamas, Barbados, Belize, Cayman Islands, Cuba, Dominica, Dominican Republic, Grenada, Guyana, Haiti, Jamaica, Montserrat, Panama, St. Vincent & Grenadines, St. Lucia, St. Kitts, Suriname, and Trinidad and Tobago.
- The Pacific Islands COF (PICOF) coordinated by the Australian Bureau of Meteorology and covering Cook Islands, Fiji, Kiribati, Niue, Papua New Guinea, Samoa, Solomon Islands, Tonga, Tuvalu, and Vanuatu. Participants use a statistical-based model to run the seasonal climate outlooks for the upcoming 3-month period.
- The Forum On regional Climate monitoring, assessment and prediction for Regional Association II (Asia) (FOCRAII), which covers all the countries in Asia and is coordinated by the BCC of CMA.

- The South Asian Climate Outlook Forum (SASCOF) established in 2009 and covering Afghanistan, Bangladesh, Bhutan, India, Maldives, Myanmar, Nepal, Pakistan, and Sri Lanka.
- The Southeastern Europe COF (SEECOF) launched in 2008 with participation of Hungary, Slovenia, Croatia, Serbia, Bosnia, Montenegro, Albania, the Former Yugoslav Republic of Macedonia, Greece, Turkey, Bulgaria, Romania, Moldova, Israel, Cyprus, Armenia, Georgia, and Azerbaijan.
- The North Eurasia COF (NEACOF) supported by the North Eurasia Climate Center (NEACC), which was launched in 2011 for the benefits of the Commonwealth Independent States (CIS) of Armenia, Azerbaijan, Belarus, Kazakhstan, Kyrgyzstan, Moldova, Russian Federation, Tajikistan, Turkmenistan, Ukraine, and Uzbekistan.

Outlook

In spite of continuous improvements of agronomic practices and field technologies and advances achieved through breeding programs, agriculture remains and will continue to remain sensitive to weather and climate variability. Positive impacts of climate change are expected in a few places but in many areas agriculture is most likely to become more exposed to climatic risks in the future. Access to targeted and reliable weather forecasts will, therefore, play a main role in risk management and remain an important component of decision making, with respect to both tactical and strategic issues.

The skill of deterministic forecasts out to 10 days has significantly improved over the past decade. Moreover, owing to a tremendous increase in computer resources it is now possible to produce limited area forecasts out to 2–3 days at a spatial resolution suitable for applications at even the farm scale. Still, much remains to be done to improve the predictability at the seasonal time scale. This requires a better understanding of ocean–atmosphere interactions and of the large-scale modes of variability in both components of the climate system.

During the last decades, much attention has been paid to understanding and predicting the onset and development of the various phases of the ENSO, but unfortunately advances in the prediction of other large-scale phenomena have been slow or inexistent. This is the case for the North Atlantic Oscillation (NAO) (Bojariu and Gimeno, 2003), a large-scale mode of climate variability that has significant impacts on terrestrial ecosystems (Hurrell *et al.*, 2003). Well documented with respect to agriculture is the link between the NAO wheat yield quality in the United Kingdom (Kettlewell *et al.*, 1999; Atkinson *et al.*, 2005), an example demonstrating how much the agricultural sector in Europe could benefit from reliable NAO forecasts.

For various reasons, translating seasonal forecasts into agricultural terms remains a challenge. As noted by Garbrecht *et al.* (2005), in many areas of the world farmers, consultants and policy makers do not have access to appropriate information, mainly because specific impact indicators and relevant decision variables cannot be directly inferred from the public forecasts usually available. Improving on this situation will require scientific advances, for instance, in relation to downscaling.

The integration of different models into end-to-end information systems will also play an important role for the supply of specific information (Weiss, 1994; Doblas-Reyes *et al.*, 2006). The participation of the end users will be essential in relation to the design of expert systems (Fraisse *et al.*, 2006). Needs for information technologies in developing countries may differ from those in developed countries and have to be addressed by the climate community to close the gap in accessing information in different areas of the world. One of the recommendations formulated by the workshop of the WMO Expert Team on 'Climate Change/Variability and Medium- to Long-Range Predictions for Agriculture' organized by the Commission for Agricultural Meteorology (CAgM) of the WMO and the Queensland (Australia) Department of Primary Industries and Fisheries (DPI&F) in 2004 was that information transfer to low-tech end users in developing countries should be considered with priority in the future (Garbrecht *et al.*, 2005).

Participatory approaches at all stages of forecast dissemination will remain crucial for ensuring a better understanding and interpretation of the forecasts (McCrea *et al.*, 2005). As underlined by the experiences gained in the context of the RCOFs, lack of trust in the forecasts has been a major impediment toward their adoption in the past (Patt *et al.*, 2007). Clearly, capacity-building activities are required to make sure that end users are sufficiently confident in the forecasts (Garbrecht *et al.*, 2005). Farmers, stakeholders, consultants, and other actors have to learn not only to take better decisions given a forecast that will eventually be verified but also to handle situations that arise from taking decisions on a wrong forecast or not taking decision at all. In this respect, communicating forecast uncertainties is of paramount importance. This will require among other things extending ensemble forecasting techniques to agricultural decision support systems (Challinor *et al.*, 2013).

A more systematic examination of the value of weather information is also needed, especially concerning agricultural applications of seasonal weather forecasts in developing countries. *Ex ante* assessments (e.g., Sultan *et al.*, 2010) have disclosed potential benefits. But possibilities to investigate actual applications have been limited by the fact that in many areas open access to operational seasonal forecasts have only recently become reality. Shifting the focus from *ex ante* to *ex post* impact studies will provide a more realistic basis for assessing the value of seasonal forecasts (Meza *et al.*, 2008).

Further Readings

Given the breadth of the topic, it is not possible to cover all aspects related to the application of weather forecasts in agriculture, nor it is possible to cover selected aspect in depth within the space provided by a single article in this Encyclopedia. Turning to other sources of information is, therefore, necessary to gain a more thorough understanding of specific issues.

Yet, providing a comprehensive review of the relevant literature is also an almost impossible task. Too many are the books, peer-reviewed articles, and reports that have been and are continuously published on subjects that, in a way or the

other, are of relevance in the context of weather forecasting for agriculture. The following list of references is, therefore, intended only as a starting point.

Books

- *Agricultural Meteorology*: Griffiths (1994) and WMO (2012) are two complementary handbooks on agricultural meteorology that perfectly serve the purpose of getting acquainted with the many facets of the application of weather forecasting to agriculture. They were both written by recognized experts and contain a wealth of further readings. Topics covered are among others the basics of agricultural meteorology, crop and animal production, pest and disease management, forestry, aquaculture and fisheries, desertification and other environmental risk, and decision making and economics.
- *Application of seasonal forecasts and climate predictions to agriculture*: Hammer *et al.* (2000) summarize the Australian experience in the application of seasonal forecasts to agricultural decision problems. It provides a nice introduction to seasonal forecasting, addresses agricultural applications at the farm scale as well as large-scale issues related, for example, to agribusiness and government policy. Sivakumar and Hansen (2007) report the outcomes of the 'International Workshop on Climate Prediction and Agriculture – Advances and Challenges' and a 'Synthesis Workshop of the Advanced Institute on Climatic Variability and Food Security,' reviewing the advances made up to 2007 in seasonal predictions and their applications for the management of agricultural enterprises. Harrison *et al.* (2007) provide a summary of the experiences collected by the 'Working Group on the Use of Seasonal Forecasts and Climate Predictions in Operational Agriculture,' an expert panel established in 1999 by the Commission for Agricultural Meteorology of the WMO. The book discusses case studies from different areas of the world, including South America, Africa, Australia and the Pacific, and South Asia.
- *Climate and weather risks*: Sivakumar *et al.* (2005) and Sivakumar and Motha (2007) are excellent complements to Sivakumar and Hansen (2007) with a focus on natural disasters and the management of climate risks in agriculture. All three books adopt a similar layout and include the discussion of numerous case studies from all over the world.
- *Weather forecasting*: Kalnay (2003) and Warner (2011) both introduce the science of numerical weather prediction and many of the aspects associated with the operational implementation of weather forecasting.
- *Forecast verification*: Jolliffe and Stephenson (2012) is the first book that deals specifically and comprehensively with the assessment of forecast quality and forecast value.
- *Value of weather forecasts*: Katz and Murphy (1997b) provide a nice overview of issues that need to be considered in assessing the economic value of weather and climate forecasts. It contains a short introduction to the science of weather prediction, a systematic treatment of forecast quality, the basics for assessing the value of weather information, and a review of descriptive and prescriptive decision studies. The latter includes a useful selection of case studies from the agricultural sector.
- *Weather derivatives*: Jewson and Brix (2005) review the meteorological, mathematical, statistical, and financial issues that arise in the pricing and managing of weather derivatives. Although this topic has only been mentioned in margin in the present article, it is included here because many are the applications of weather derivatives to agriculture, other components of the food chain, and the trading of agricultural commodities.
- *Statistics in the atmospheric sciences*: Wilks (2011) authored a textbook on statistical methods needed to describe and analyze atmospheric data and forecast products. Although rigorous, it is accessible for a wider audience than more mathematical-oriented books, such as by von Storch and Zwiers (1999).

Reports

- Several technical notes of interest are published on a regular schedule by the WMO and more specifically by its Commission for Agricultural Meteorology.
- Articles of relevance for the subject can also be found in the WMO Bulletin, the official journal of the WMO. The latest issue of the WMO Bulletin and archives are available online.

Special Issues (In Reversed Chronological Order)

- *Agricultural and Forest Meteorology*, Vol. 170, 2013. A special issue on 'Agricultural prediction using climate model ensembles' (http://www.sciencedirect.com/science/journal/01681923/170, accessed 02.12.13).
- *Climate Research*, Vol. 33, No. 1, 2006, Special issue 16 on 'Advances in applying climate prediction to agriculture,' which reports on the results of the international Climate Prediction and Agriculture (CLIMAG) program initiated in 1999 by the WMO. It is a complement to the book edited by Sivakumar *et al.* (2007) (http://www.int-res.com/abstracts/cr/v33/n1/, accessed 02.12.13).
- *Climatic Change*, Vol. 70, Issue 1–2, 2005, A special issue devoted to 'Increasing climate variability and change; reducing the vulnerability of agriculture and forestry' (http://link.springer.com/journal/10584/70/1/page/1, accessed 02.12.13).
- *Philosophical Transactions of the Royal Society B*, Vol. 360, No. 11, 2005, Discussion meeting issue 'Food crops in a changing climate' (http://rstb.royalsocietypublishing.org/content/360/1463.toc, accessed 02.12.13).
- *Tellus, Series A*, Vol. 57 A, Issue 3, 2005, A special issue devoted to Research Conducted in the Framework of the Project DEMETER (Development of a Multimodel Ensemble System for Seasonal to Interannual Climate Prediction) (http://onlinelibrary.wiley.com/doi/10.1111/tea.2005.57.issue-3/issuetoc, accessed 02.12.13).
- *Agricultural Systems*, Vol. 74, No. 3, 2002, A special issued dedicated to 'Applying seasonal climate prediction to agricultural production' (http://www.sciencedirect.com/science/journal/0308521X/74/3, accessed 02.12.13).
- *Agricultural and Forest Meteorology*, Vol. 103, Issues 1–2, 2000, A special issue with papers presented at the

International Workshop on Agrometeorology in the 21st Century: Needs and Perspectives, 15–17 February 1999, Accra, Ghana (http://www.sciencedirect.com/science/journal/01681923/103/1-2, accessed 02.12.13).

Glossaries and Dictionaries

Glossary

Climate change Refers to any change in climate over time, irrespective of whether it is due to natural variability or as a result of human activity. This usage differs from that in the United Nations Framework Convention on Climate Change, which defines 'climate change' as: "a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods."

Climate variability Refers to variations in the mean state and other statistics (such as standard deviations, statistics of extremes, etc.) of the climate on all temporal and spatial scales beyond that of individual weather events. Variability may be due to natural internal processes within the climate system (internal variability) or to variations in natural or anthropogenic external forcing (external variability).

Drought A drought can be meteorological, hydrological, agricultural, or even socioeconomic. A meteorological or climatological drought is defined with respect to departures from the normal and the duration of the event. An agricultural drought is defined as the deficit in soil moisture. A hydrological drought is the result of decreasing precipitation on surface and subsurface water supply. A socioeconomic drought is the effect of meteorological, agricultural, and hydrological drought(s) on the supply and demand of economic goods.

Groundwater Water beneath the earth's surface, often between saturated soil and rock, which supplies wells and springs.

Transboundary waters Sources of freshwater that are shared among multiple user groups, with diverse values and different needs associated with water use. Water thus crosses boundaries, which can be different economic sectors, legal jurisdictions, or political interests.

Introduction

Water, the liquid of life, like air and soil has no substitute. Life, as one knows it, would not exist without water. The geosphere, atmosphere, and the biosphere are all linked to, and by, water. Water interacts with solar energy to determine climate and it transforms and transports the physical and chemical substances necessary for all kinds of life on the earth. Although 70% of the planet's surface is covered by water, most of which is saltwater, freshwater is limited and is not always in the right place, at the right time, or of the right quality. Water, on the earth, exists in several states: water vapor and clouds in the sky, seawater in the oceans, icebergs in the polar oceans, glaciers in the mountains, freshwater lakes, rivers, and fresh and saline water in aquifers. There are significant continental and country differences in the availability of freshwater.

Over the last 25 years, these differences and the importance of water has grown to occupy national and international agendas. Many international organizations, such as the United Nations, the World Bank, the World Health Organization, the World Meteorological Association, and the Stockholm International Water Institute, hold conferences related to water issues. Awareness among scientists, political leaders, and citizens of the connections between climate change, the hydrologic cycle, food production, environmental services, infrastructure needs, and sustainable water resource management increases every year. The message highlighted by all these efforts is that water is an increasingly scarce resource and that it is important to recognize and accept that there is a finite supply of water. Competition among agriculture, industry, and cities for limited water supplies is already constraining development efforts in many countries. At first glance, most of these water problems do not appear to be directly related to the agricultural sector. Yet, by far, agriculture has the largest demand for the world's water. Approximately 70% of the water withdrawn from the earth's rivers, lakes, and aquifers is used for food and fiber production. Of increasing concern is the rapid depletion of fossil water in the limited recharge aquifers in many regions of the world. Water in these aquifers accumulated over thousands of years and cannot be readily recharged. Regions of concern include the Western United States, Northern China, Northern and Western India, Egypt, and North Africa (Pearce, 2006). As competition, conflicts, shortages, waste, overuse, and degradation of water resources grow, policymakers look increasingly to agriculture for solutions.

Water stress is highlighted by drought. Of all the hydrological hazards, drought has historically impacted the largest number of people because they are more geographically widespread. Droughts are insidious because they do not have a clear beginning like floods. They start slowly and their effects are not apparent for weeks, months, or even years. The southern plains drought of the 1930s in the United States often described as the 'dust bowl' lasted about a decade and was an agricultural, environmental, and human disaster. John Steinbeck in his 1939 novel '*The Grapes of Wrath*' chronicled the human suffering and migration of farmers fleeing the southern plains for California. More recently, a devastating spring 2010 drought in Southwestern China affected 60 million people and caused livestock and crop losses totaling approximately $5 billion. Ironically, in that same year floods in Northwest China impacted 300 million people, killed more than 3000, and caused more than $40 billion in damages. Correspondingly, Texas in 2011 experienced a major drought resulting agricultural losses of nearly $9 billion dollars

 doi:10.1016/B978-0-444-52512-3.00083-8

(Combs, 2012). Although floods and droughts have always plagued mankind and agriculture, they serve to heighten awareness on water issues and the need to wisely use and manage water resources.

As a prelude to sustainable water management for agriculture and food systems, this article briefly outlines water supply and use factors and challenges for the future. It begins by briefly providing an overview of the physical and chemical uniqueness of water before discussing water location, availability, and uses. A section on 'virtual water' provides information on the amount of water embedded in food, fiber, and products. Impacts of drought and climate change on water availability are outlined. Before the conclusion, issues with transboundary surface and groundwater resources sharing and management are highlighted. These issues will become increasingly complex as the climate changes.

Physical and Chemical Properties of Water

Water (H_2O) has a very simple atomic structure, which consists of one oxygen atom and two hydrogen atoms bonded together by shared electrons. The hydrogen side of each water molecule carries a slight positive electric charge, whereas the oxygen side carries a slight negative electric charge. This molecular polarity gives water its unique physical and chemical properties. Thus, water occurs naturally as a liquid, a solid, and a gas.

The 'bipolar' nature of water molecules gives water its special adhesion and cohesion properties. Hydrogen bonds cause water molecules to cohere and stay together and form high surface tension. Surface tension allows water droplets to form when placed on a dry surface or allows substances to float on water, while adhesion allows water to stick to other substances. These cohesive and adhesive forces play an important role in the movement of water from the soil matrix in the root zone to the leaves of plants. The forces create a pull as water molecules evaporating from leaves try to cling to water molecules below them. This movement of water across the plant also helps transport of dissolved minerals that plants need in order to grow.

The polarity of water makes it a good solvent allowing it to dissolve other polar substances. Hydrophilic (water loving) substances such as salts, acids, and alcohols dissolve in water and hydrophobic (water fearing) substances such as oils and fats do not mix well in water and are not dissolved. These properties affect the interaction of water molecules with other substances and thus every living organism on Earth. Water, as it flows through the air, the ground, or our bodies, carries valuable chemicals, minerals, and nutrients and helps sustain life.

Water has a unique thermal behavior. It has a high specific heat, which means that it can absorb a large amount of energy before it gets hot and it also releases heat slowly. It is both a heat-transfer medium and a temperature regulator. It heats and cools more slowly than soil and is thus, able to buffer large fluctuations in temperature which helps moderate the climate. An example of the influence of water on the climate can be felt on areas near large water bodies. They tend to have warm autumns and cool springs because of the differential heating and cooling between land and water.

Water expands anomalously when heated, between 0 and 4 °C; water contracts and becomes denser, unlike most substances, which expands and becomes less dense as their temperature rises. Water is densest at 4 °C, and becomes less dense when the temperature either increases or decreases with respect to this temperature.

Ice is therefore less dense than cold water and hence floats over water. Floating ice slows the freezing process and acts as a blanket insulating water found underneath. This ice layer further prevents the whole lake from freezing and fish and other organisms are able to survive through winters.

Global Distribution of Water

The water paradox is that although 70% of the 'blue planet' is covered by water, freshwater resources are very limited. Approximately 97% of the world's water is saltwater, undrinkable and unusable without expensive and energy-intensive desalination techniques. Only 3% is freshwater, and only a relatively small portion is readily available to sustain human, plant, and animal life. Slightly more than two-thirds of this 3% is ice, located in the polar ice caps, glaciers, and permafrost and is not readily available for human use (**Table 1**). Although melting of polar ice caps may not increase the flow of freshwater, melting of interior glaciers may. The Himalayas contain the greatest area of glaciers and permafrost outside of the poles and are melting (Gardner *et al.*, 2013). Most of Asia's largest rivers flow from there and slightly more than a billion people rely on river flow from this glaciated area. Of the remaining 30% that is not frozen, most is groundwater. Only approximately 1.2% of the earth's freshwater is surface water found in lakes, rivers, and streams. Although the 0.49% of surface freshwater that is in rivers is a tiny amount, it provides significant water for agriculture and domestic use.

The amount of water that is accessible for direct human consumption is minute (slightly $<1\%$) compared to the total volume of water on Earth. This water is found in surface water bodies such as lakes, rivers, and stored in man-made reservoirs, and in underground aquifers shallow enough for easy and affordable retrieval. Most of these water sources are

Table 1 Global water distribution

Source	*Water volume (km^3)*	*% Freshwater*	*% of total water*
Oceans	1 338 000 000	–	96.5
Ice caps	24 064 000	68.7	1.74
Permafrost	300 000	0.86	0.022
Groundwater	10 530 000	30.1	0.76
Lakes/Marshes	187 870	0.30	0.008
Soil moisture	16 500	0.04	0.001
Atmosphere	12 900	0.03	0.001
Rivers	2 120	0.006	0.0002

Note: % are rounded, so will not add to 100.

Source: Reproduced from Shiklomanov, I., 1993. World fresh water resources. In: Gleick, P.H. (ed.), Water in Crisis: A Guide to the World's Fresh Water. New York, NY; Oxford: Oxford University Press, pp. 13–24.

Table 2 Richest countries in terms of water resources

Country	*Total water available per inhabitant (km^3 $year^{-1}$)*
Brazil	8233
Russia	4507
Canada	2902
Indonesia	2838
China	2830
Columbia	2132
USA	2071
India	1897

Source: Reproduced from Food and Agriculture Organization, 2003. Review of World Water Resources by Country, Rome: FAO.

renewed by precipitation and can, to a certain extent, be considered renewable. Climate and the geology affect the distribution of water on Earth; hence the uneven availability.

The total renewable water resources in the world on an annual basis are estimated in the order of 43 750 km^3 $year^{-1}$. At the continental level, America has the largest share of the world's total freshwater resources of 45%, followed by Asia with 28% share, Europe with 15.5%, and Africa with 9% (Food and Agriculture Organization, 2003).

On a worldwide basis there are water-rich and water-poor countries. The eight richest countries in terms of water resources, listed in **Table 2**, account for 60% of the world's natural freshwater resources (Food and Agriculture Organization, 2003). The ten poorest countries in terms of water resources per inhabitant are Bahrain, Jordan, Kuwait, Libyan Arab Jamahiriya, Maldives, Malta, Qatar, Saudi Arabia, the United Arab Emirates, and Yemen. The difference between water resources per inhabitant for water-rich and water-poor countries can be explained with the help of an example: Brazil, a water-rich country, has 8223 km^3 of water resources per year per inhabitant, whereas Jordan, a water-poor country, has only 0.75 km^3 of water resources $year^{-1}$ per inhabitant.

Groundwater

Groundwater percolating beneath the earth's surface as soil moisture and contained in aquifers represents approximately one-third of all the world's freshwater resources. The area extending from the top of the land surface through the unsaturated soil to the top of the saturated water table is called the vadose zone. Soil moisture in the upper part of the vadose zone, which is the root zone of plants, is critical for food and fiber production. A very small part of the planet's freshwater is contained in this area (**Table 1**).

Water percolating through the soil may eventually fill all voids to the point that the soil is totally saturated. The upper surface of this zone of saturation is called the water table. The saturated zone beneath the water table is called an aquifer. Aquifers are huge storehouses of groundwater. There are two types of aquifers: unconfined and confined. Unconfined aquifers are those into which water seeps from the ground directly above the aquifer. Confined aquifers are those in which an impermeable layer exists above the aquifer that prevents water from seeping into the ground from the surface directly above. Instead, water seeps into confined layers from recharge zones located farther away where the impermeable layer does not exist. Aquifers are also classified on the basis of their size and the volume of water that can be extracted on an annual basis.

Approximately 35% of the earth's land area contains major groundwater aquifers and basins. Examples include the Ogallala in the United States, the Guarani in South America, the Great Artesian Basin in Australia, the Nubian in Africa, the Western Siberian in Russia, and the North China Plain Basin in Central China. In addition to these major aquifers approximately half of the continents have minor or near-surface aquifers (**Table 3**). Many aquifers exist under deserts where there is little precipitation. The water stored in these aquifers is geologically old water. Recently, satellite imagery and drilling helped to discover the Lotikipi Basin Aquifer – which by one estimate is roughly the size of Rhode Island – and the smaller Lodwar Basin Aquifer in Kenya. These aquifers contain an estimated 250 billion cubic meters of water (Kulish, 2013).

Freshwater Lakes

Most freshwater lakes are located at high altitudes, with nearly 50% of the world's lakes located in Canada alone. Lakes vary by area and volume. Following are some statistics of the freshwater lakes of the world:

- The Caspian Sea is the largest enclosed interior lake but it is saline and not freshwater (Leeden *et al.*, 1990).
- The ten largest lakes by area are given below (Downing and Duarte, 2009).

1. Caspian Sea	Asia	371 000 km^2
2. Lake Superior	North America	82 100 km^2
3. Lake Victoria	Africa	68 800 km^2
4. Lake Huron	North America	59 600 km^2
5. Lake Michigan	North America	57 800 km^2
6. Lake Tanganyika	Africa	32 900 km^2
7. Great Bear Lake	North America	31 328 km^2
8. Baikal	Asia	30 500 km^2
9. Lake Malawi (Lake Nyasa)	Africa	30 044 km^2
10. Great Slave Lake	North America	28 568 km^2

- The ten largest lakes by volume are given below (Downing and Duarte, 2009).

1. Baikal	Asia	23 600 km^3 (~ 20% of the world's freshwater)
2. Tanganyika	Africa	18 900 km^3
3. Superior	North America	11 600 km^3
4. Lake Malawi (Lake Nyasa)	Africa	7 725 km^3
5. Lake Michigan	North America	4 900 km^3
6. Lake Huron	North America	3 540 km^3
7. Lake Victoria	Africa	2 700 km^3
8. Great Bear Lake	North America	2 236 km^3
9. Issyk Kul (Ysyk Kol)	Asia	1 730 km^3
10. Lake Ontario	North America	1 710 km^3

Table 3 Storage of water in groundwater basins by continent

	Major groundwater basins		*Minor groundwater basins*	
	Volume (million km^3)	*% of land*	*Volume (million km^3)*	*% of land*
Africa	13.5	45	13.2	44
Asia	14.5	32	23	51
Australia	2.6	32	2.5	31
Europe	5.1	53	2.7	28
North America	3.2	15	12.4	58
South America	8.3	45	8.1	44

Source: Reproduced from BGR, 2008. Groundwater Resources of the World 1: 25 000 000, Statistics. Paris: BGR Hannover/UNESCO. Available at: http://www.whymap.org/whymap/EN/Statistics/statistics_node_en.html (accessed 20.01.14).

- The Great Lakes – Superior, Michigan, Huron, Erie, and Ontario – located in the Midwest of the United States and shared with Canada are the largest surface freshwater system on the earth. They contain approximately 21% of the world's surface water supply and 84% of North America's surface freshwater (US Evironmental Protection Agency, 2012).
- Lake Baikal in Asia is the largest freshwater lake holding some 23 600 km^3 of water, which is approximately 20% of the earth's total freshwater (Downing and Duarte, 2009).

Rivers

Rivers are the arteries of the planet, delivering most of the fresh surface water that people use. An estimated 263 international river basins cover approximately 50% of the earth's surface, yet by volume they carry approximately 2120 km^3, or 0.006 of 1% of total water (Table 1). The territory of 145 countries straddles international river basins. Some countries share their territory/boundary with only one other country while others may share it/them with several countries – 13 basins are shared between 5 and 8 countries, and 5 basins (the Congo, Niger, Nile, Rhine, and Zambezi) are shared between 9 and 11 riparian nations. Transboundary river basins are home to approximately 40% of the world's population (United Nations, Department of Economic and Social Affairs, 2014).

At least 33 countries depend on other countries for more than 50% of their renewable water resources. These countries include the following: Argentina, Azerbaijan, Bahrain, Bangladesh, Benin, Bolivia, Botswana, Cambodia, Chad, Congo, Djibouti, Egypt, Eritrea, Gambia, Iraq, Israel, Kuwait, Latvia, Mauritania, Mozambique, Namibia, the Netherlands, Niger, Pakistan, Paraguay, Portugal, the Republic of Moldova, Romania, Senegal, Somalia, the Sudan, the Syrian Arab Republic, Turkmenistan, Ukraine, Uruguay, Uzbekistan, Vietnam, and Yugoslavia (Food and Agriculture Organization, 2003).

Dams and Reservoirs

The flow of water in a river is not constant. It is influenced by seasons and hydrometeorological changes in the watershed. Dams are an efficient way to store water to meet demands during low rainfall seasons or periods of drought. Dams, diversions, and canals, are present on about 60% of the world's largest rivers. The 45 000 largest dams around the world have a combined storage capacity of 6000 km^3. These dams provide water for agricultural, irrigation, domestic, and industrial water use, hydropower generation, and for flood control. Dams help irrigate nearly 40% of agriculture around the world and 19% of the world's electricity is generated from water stored in dams. A third of countries rely of hydropower for their electricity needs (World Commission on Dams, 2000).

Although dams provide numerous benefits, they may also negatively impact river flow, existing water rights and access to water, the ecosystem (both aquatic and riparian), and even the livelihood of communities, especially downstream, striving on the river ecosystem for survival. Thus, the construction of new dams are often contested by funding and environmental organizations. Nonetheless, the construction of new dams continues: 46 new dams are planned for the Yangtze River basin in China, 27 in the La Plata basin in South America, 26 in the Tigris and Euphrates basin (Wong *et al.*, 2007).

Water Use

Agriculture is the largest consumer of water. It consumes 70% of the total water withdrawn, compared to only 19% for industrial use and 11% for municipal use. This ratio is skewed by a few countries with high water withdrawals. On an average, the ratio of agricultural to municipal and industrial use is 59%, 23%, and 18% respectively (Food and Agricultural Organization, 2012). It is believed that irrigation started along the Tigris and Euphrates Rivers in what is now Iraq, in the desert valley along the Nile River in Egypt, and the Indus River in Pakistan. The Native Indians, in what is now Mexico and the southwestern United States, also used irrigation to support food production. Irrigated agriculture has expanded tremendously and currently supports 40% of crop production around the world. Table 4 gives the water use for agriculture, domestic, and industry across each continent. Except for Australia, agricultural water use dominates other uses on every continent.

Asia, home to most of the world's population, is also the most irrigated. China, India, and the United States, the three most populous countries, have the largest areas under irrigated agriculture (Table 5), followed by Pakistan, Mexico, and Egypt. A number of countries located in the arid region of the world (e.g., Saudi Arabia, Iran, Iraq, Israel, etc.) and central

Asia are highly dependent on irrigation for their food and fiber needs.

The world's population is projected to increase by an additional 2–3 billion in the next 40 years. This will result in an increase in the demand of food supply and subsequently in the demand for water. With climate change, precipitation and hence water availability is expected to decrease, especially in the lower latitudes. Regions that are likely to be affected by climate change are also the most vulnerable in terms of water availability. In order to meet the food demand for the growing population, water use for irrigation is estimated to increase by about 19% by 2050. Technological (e.g., more efficient irrigation demand) and policy (e.g., use of genetically modified crops) interventions may, however, reduce pressure on agricultural water demands.

Virtual Water and Water Footprint

Production of food is extremely water intensive. The virtual water content, which represents the volume of water content the product has consumed throughout its growth cycle, gives an interesting perspective of the flow of water from major agricultural countries in terms of production to those relying mostly on import.

The production of 1 ton of grain, on an average, requires 1000 m^3 of water, whereas the virtual water content of livestock product is much larger, as it includes the virtual water content of the feed crops consumed, the water that animal drank over its whole lifetime, and the water used in the production of the final product. The production of 1 ton of beef thus requires approximately 15 500 m^3 of water (Hoekstra and Hung, 2002).

A country producing and exporting an array of food product is, in fact, exporting the water embedded in them beyond its boundaries, whereas a country at the importing end is actually importing that embedded water and thus saving its own water, which can be put to other uses (Allan, 1997). **Figure 1** shows the international virtual water flows and virtual water balances for all countries in the world. From 1996 to 2005, the volume of international water flows related to agricultural and industrial products averaged 2320 billion cubic meters. The main virtual water gross exporters were the United States, China, Canada, Brazil, Argentina, and Australia, whereas main gross virtual water importers were the United States, Japan, Germany, China, Italy, and Mexico (Mekonnen and Hoekstra, 2011).

Reliance on food import can be an attractive option for water-poor countries, whereas water-rich countries may produce and efficiently export more virtual water to other regions, thus replicating the logic of economies of scale (Mekonnen and Hoekstra, 2011). Virtual water could advocate for water conservation by discouraging the production of high water-embedded products from water-scarce regions and encouraging the water-dependent economic activity in water-rich regions. The decision-making process of international trade does not seem to drive water efficiency use or water conservation efforts (Black and King, 2009; Ercin and Hoekstra, 2014). Food independence drives large-scale agricultural production and no country is willing to rely solely on import to meet its food needs. This sociopolitical need can easily lead to the misuse of limited available freshwater resources.

Climate

Local hydrometeorological variables (temperature, humidity, sunshine, atmospheric pressure, wind velocity, precipitation, etc.), and hence water availability, are influenced by the climate. Climate (or climatological normal) is a measure of the average pattern of the meteorological variables over a particular region and over a time period, usually 30 years. Discussions on the climate, in the context of water availability, include climate variability and climate change (or global warming). Climate variability pertains to the way the climate fluctuates around the long-term mean, whereas climate change refers to the long-term continuous change to a long-term statistically significant variation in either the mean state of the climate or its variability.

Climate Variability

The common drivers of climate variability are large-scale circulation patterns, sunspots, and volcanic eruptions. The former, however, is the most important one and can dramatically alter the climate, weather, and hydrometeorological variables around the world. The time period of the resultant change can be in terms of months, years, or even decades.

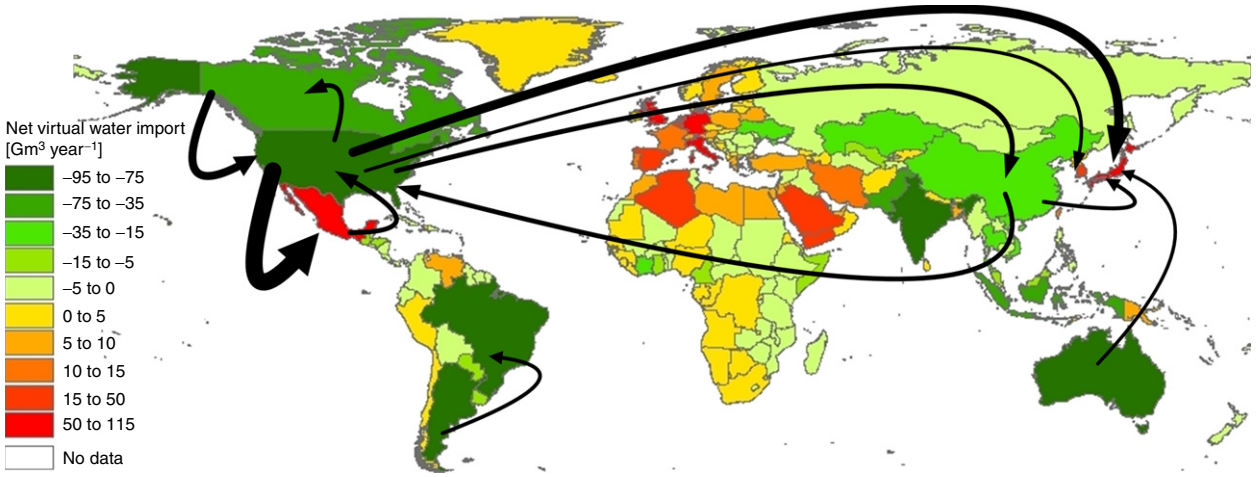

Figure 1 Virtual water balance and direction of gross virtual water flows over the period 1996–2005. Reproduced with permission from Hoekstra, A.Y., Mekonnen, M.M., 2012. The water footprint of humanity. Proceedings of the National Academy of Sciences 109 (9), 3232–3237.

El Niño–Southern oscillation

There are a number of climate variability patterns that influence local hydrometeorological conditions. The most important one is the El Niño–Southern Oscillation (ENSO). ENSO is a coupled ocean–atmosphere phenomenon related to sea surface temperature (SST) anomalies in the Central and Eastern Equatorial Pacific and the associated sea-level pressure difference, the Southern Oscillation (SO) (Rasmusson and Carpenter, 1982). The SO is the fluctuation in air pressure between Tahiti and Darwin, Australia. Negative (positive) pressure is accompanied by sustained warming (cooling) in the Central or Eastern Pacific. ENSO has a recurrence pattern of 3–6 years and every event normally lasts for approximately a year. El Niño events are often, but not always, followed by La Niña events, also referred to as the cold phase of ENSO (Trenberth, 1997). They have a direct effect on the hydrologic cycle both regionally and globally, especially on precipitation patterns (e.g., Khedun *et al.*, 2012; Piechota and Dracup, 1996; Regonda *et al.*, 2005; Ropelewski and Halpert, 1987).

Regional effect of El Niño–Southern oscillation

The effect of ENSO is distributed uniformly neither across the globe, not even across a single continent, nor in time during its period of occurrence (Lyon, 2004). As ENSO cycles through its different phases (El Niño, La Niña, and neutral), its impacts vary both spatially and temporally (**Figure 2**).

Africa

The effect of ENSO is mostly felt in the southeastern part of Africa and Madagascar and the eastern part along the equator. Dry and warm (wet and cool) conditions are felt during El Niño (La Niña) during December through February in the southeastern part, whereas the eastern part benefits from higher (lower) precipitation. ENSO conditions influence the ecosystem and may affect rainfed agriculture and yield. Remote sensing studies on ecosystem variables confirm ENSO's influence; above normal normalized difference vegetation index were noted, indicative of a high biomass content, during the 1997/98 El Niño event in the eastern equatorial region along with wetter than normal conditions in the southeastern region while the southwestern region was dry (Anyamba *et al.*, 2001; Anyamba *et al.*, 2002).

Asia and Australia

El Niño causes abnormally warm and dry conditions during December through February over the region encompassing Southern Asia to Northern Australia. By June and August, the dry conditions extend to most of the eastern part of Australia, leading to an increase in the risk of bush fires (Fuller and Murphy, 2006; Williams and Karoly, 1999). Some 1.75 million hectares of land was destroyed by bush fire in January and February 2003, an El Niño year (Bear and Pickering, 2006).

The relationship between ENSO and the Asian-Australian and Indian summer monsoon is well established (Charles *et al.*, 1997; Kirtman and Shukla, 2000; Kumar *et al.*, 1999; Yoo *et al.*, 2010). The monsoon is associated with the biannual complete reversal of lower atmosphere wind regime over the Indian Ocean, which results from the differential heating between the land and sea surfaces and the presence of the Himalayas (Cadet, 1979). There is a negative correlation between ENSO and the Indian summer monsoon (weak monsoon arising from El Niño events). It causes a change in the precipitation pattern and has a strong impact on glacier-fed rivers. Ice cores from the Himalaya indicate that snow accumulation in the region is sensitive to the changes in the South Asian Monsoon (Thompson *et al.*, 2000). These glaciers are the headwaters of several major rivers (e.g., the Huang He (Yellow) and Yangtze rivers in China, the transboundary Mekong, Ganges-Bhramaputra-Meghna, Indus, etc.) and they sustain the lives and economy of nearly 1.5 billion people in 9 Asian countries – the most populous region of the world.

Europe

The influence of ENSO does not extend into Atlantic Europe, but its impact on Atlantic storm tracks can impact European weather (Schär *et al.*, 1998). It is important to note that the geographical distance separating Europe and the Central Pacific Ocean, where fluctuations in SST lead to ENSO, may

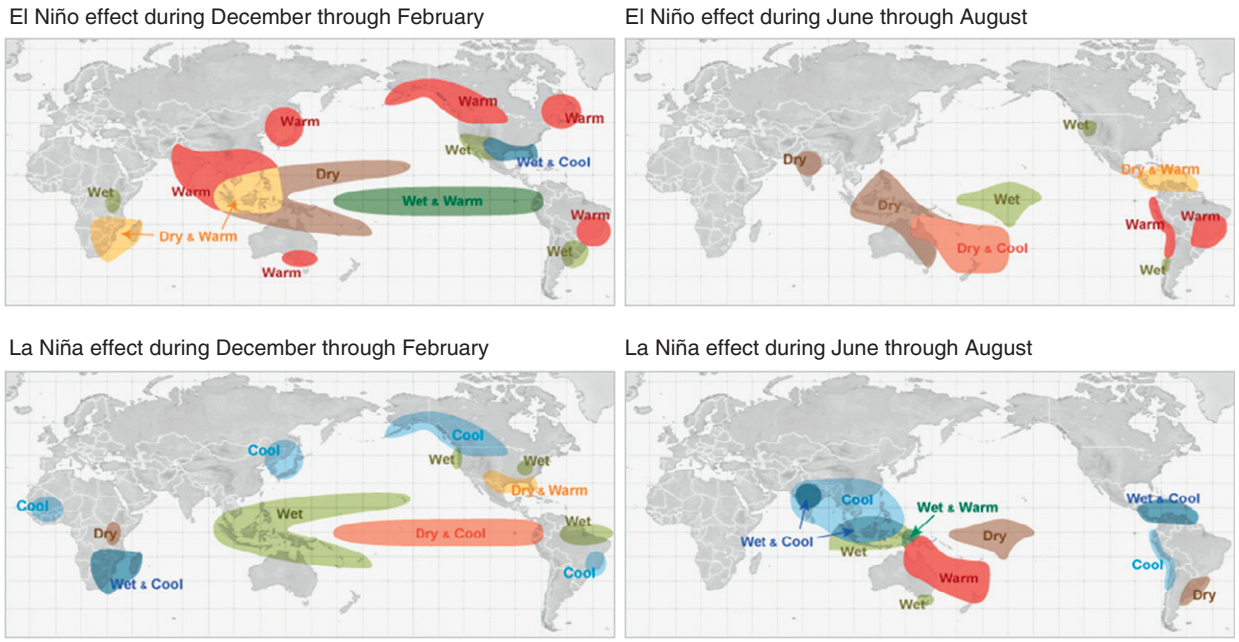

Figure 2 Effect of El Niño and La Niña around the world. Reproduced from National Oceanic and Atmospheric Administration, National Weather Service, 2012. Weather impacts of ENSO. Available at: http://www.srh.noaa.gov/jetstream/tropics/enso_impacts.htm (accessed 28.01.14).

make it hard to detect any association between ENSO and European weather using simple linear correlation techniques (Fraedrich, 1994). Warm (cold) ENSO episodes have been associated with enhanced cyclonic (anticyclonic) activities (Fraedrich, 1990). Warm events have been observed to produce more variable winter conditions, whereas cold events have had a more uniform response. The influence of ENSO on the glaciers of the European Alps, surface water reservoir for a number of important rivers, is almost negligible at the yearly timescale (Durand *et al.*, 2009), but weak correlations may be detected on a multidecadal scale (Efthymiadis *et al.*, 2007). Hence, the influence of ENSO should not be ignored in the water resources planning for the region.

North America

ENSO alters the path of the jet stream and hence affects the weather and storm tracks on the North American continent. El Niño causes a dip in the position of the jet stream in the Eastern Pacific, which results in warmer winters in Western Canada, Southern Alaska, and Northeastern United States, whereas the Southern United States has cooler and wetter weather. During the summer the southern part of Mexico becomes warm and dry. During La Niña the dip in the jet stream shifts west of its normal position toward the Central Pacific. It causes cooler winters in Eastern Canada, whereas the Southern United States becomes warm and dry.

The shift in the jet stream, during warm ENSO events, forces storms south of their normal position in the Pacific Northwest into California. Stronger El Niño events can force storms even further south into Southern California and the Pacific Northwest becomes drier as the moisture flux is transported southward. California thus benefits from above average precipitation during El Niño and flash floods are very common (Mo and Higgins, 1998; Schonher and Nicholson, 1989). This influx of moisture also increases snowfall in the Sierra Nevada mountain range (Kunkel and Angel, 1999). In the Rocky Mountains, the effect of ENSO varies with opposite effects at the northern and southern ends (Baker, 2003). The Rockies can be divided into three sections: the northern Rocky Mountains in Montana, the central Rocky Mountains extending from southern Montana into central Wyoming, and the southern Rocky Mountain stretching from southern Wyoming into New Mexico and Arizona. El Niño (La Niña) winters bring higher (lower) snowfall in the southern Rockies (Kunkel and Angel, 1999). The effect of ENSO on the central and northern Rockies is less pronounced. In its cold (warm) phase ENSO brings higher (lower) snowfall over the Pacific Northwest in early winter and midwinter and over the northern Rocky Mountains in midwinter (Patten *et al.*, 2003; Smith and O'Brien, 2001). The central Rockies receive 30% less heavy precipitation events (Gershunov and Barnett, 1998a).

South America

El Niño is associated with severe drought in Mexico and most of Brazil, whereas Argentina, Paraguay, and Uruguay benefit from increased precipitation. The coastal areas of Ecuador, Northern Peru, and Southern Chile also benefit from increased rainfall, but the mountainous Andes region suffers from drought, which causes the glaciers to retreat. In La Niña conditions, however, this region receives a fourfold increase in heavy storm events as compared with non-ENSO years (Grimm *et al.*, 2000; Haylock *et al.*, 2006). ENSO events have also been found to influence extreme precipitation events in South America (Grimm and Tedeschi, 2009). This is an important observation as hydrological hazards are often associated with changes in extreme events associated with climate variability.

Other large-scale circulation patterns

Even though ENSO is the most well-known large-scale climate variability pattern, there are a number of other climate teleconnection patterns that affect, to varying degrees, local weather conditions and hence water availability. Their influence, either alone or in conjunction with ENSO, should not be discounted. Some of the most common ones include the following: the Pacific Decadal Oscillation (PDO), the North Atlantic Oscillation (NAO), the Atlantic Multidecadal Oscillation, the Quasi Biennial Oscillation, the El Niño Modoki, etc.

In the United States, for example, it has been found that PDO may modulate the effect of ENSO; El Niño (La Niña) during the positive (negative) phase of the PDO, and lead to stronger climate responses than when they are evolving in opposite phases (Gershunov and Barnett, 1998b). There is, however, a possibility that stronger El Niño and La Niña events result from random decadal variation of ENSO and may even be responsible for the PDO (McPhaden *et al.*, 2006; Rodgers *et al.*, 2004). Irrespective, knowledge of all the climate variability patterns that influence local climate conditions is important and can help in the forecasting of precipitation and other climate variables that affect water availability (Chowdhury and Sharma, 2009; Devineni *et al.*, 2008; Khedun *et al.*, 2014).

Climate Change

The earth's climate is constantly changing. The change can be due to natural causes, such as changes in the earth's orbit, changes in solar activity, or volcanic eruptions, or can be anthropogenic, resulting from a change in the composition of the earth's atmosphere. Since the beginning of the Industrial Era, human activities have led to an increase in the concentration of heat-trapping greenhouse gases in the atmosphere, which has led to an increase in atmospheric temperature. In fact, the most likely reason for the recent observed warming, since the mid-twentieth century, is anthropogenic greenhouse gas emissions.

The greenhouse effect

According to the recent Fifth Assessment Report (AR5) from the International Panel on Climate Change (IPCC; Stocker *et al.*, 2013), the global mean surface temperature has been increasing, and each of the past three decades has been successively warmer (**Figure 3**). A linear trend, fitted to global average combined land and ocean temperatures, reveals a 0.85 (0.65–1.06) °C increase over the period 1880–2012.

The temperature on the earth depends on the balance between energy entering and leaving the atmosphere. Incoming energy from the sun can be either reflected back into the space or absorbed by the earth's surface. Some of the energy absorbed is released back into the atmosphere (infrared radiation). Greenhouse gases (water vapor, carbon dioxide, methane, etc.) absorb some of this energy and thus keep the atmosphere warm. The earth's average surface temperature, without the greenhouse effect, would be 255 °K (− 18 °C), instead of the current 288 °K (15 °C), which enables life to thrive. Paleoclimatological records from ice cores, corals, lake sediments, tree rings, etc. reveal that the concentration of greenhouse gases, especially carbon dioxide and methane, has fluctuated naturally over geological times, thus causing the climate to fluctuate between ice ages and interglacial periods. In recent decades, however, a marked increase in the concentration of carbon dioxide has been recorded. This increase has been attributed mostly to human activities, such as burning of fossil fuels, clearing of forests, and the use of gasoline-dependent modes of transportation. The global monthly average concentration of carbon dioxide in the atmosphere has increased from a preindustrial level of approximately 280 ppm (parts per million; pre-1750 tropospheric concentration) to 395.92 ppm (November 2013 (note that June 2013 concentration was higher at 398.58 ppm)) (Blasing, 2013; Tans and Keeling, 2014). The resulting increase in temperature is having a significant impact on the planet, affecting its land and marine ecosystems, the hydrologic cycle, sea level, weather extremes and weather-related hazards, water availability, food and fiber supply, human health, and the economy among others.

Impact on the hydrologic cycle

As the climate changes, the amount of energy on the earth's surface is expected to increase, which shall result in an intensification of the hydrologic cycle. A warmer planet implies that the water-holding capacity of the atmosphere will increase; thus leading to an increase in evapotranspiration. Higher evaporation from the soil implies less water for plants and a decrease in the recharge of groundwater aquifers and may result in a decrease in baseflow and hence less water in streams and rivers, lakes, and wetlands. An increase in evaporation from large water bodies, such as lakes and the ocean, implies more water in the atmosphere and an increase in global precipitation.

According to the IPCC (Stocker *et al.*, 2013), precipitation across the globe is projected to gradually increase at a rate of approximately 2% K^{-1}. This increase in global precipitation, however, will not be equally distributed, neither spatially nor temporally, across the planet; some regions may experience an increase in overall precipitation, whereas others may suffer a decrease, and still other regions may not register a notable change (**Figure 4**). High-latitude regions are likely to experience greater precipitation volumes as a result of the additional water-carrying capacity of the warmer troposphere. Midlatitude and subtropical arid and semiarid regions, however, will likely experience a decline. Similarly, a decrease in runoff in Southern Europe, the Middle East, and North Africa is likely, whereas northern latitude countries will experience an increase. IPCC AR 5 further states that even though global-scale projections of the impact of climate change on soil moisture and drought are not as obvious as that on other variables of the water cycle, drying in the Mediterranean region, the Middle East, Southwestern United States, and Southern Africa can be expected.

Effect on extreme events

An intensification of the hydrologic cycle due to climate change implies that the frequency, intensity, spatial extent, duration, and timing of extreme precipitation events, evapotranspiration, tropospheric water content, and runoff may

change (National Research Council, 2011), thus influencing the occurrence, nature, and return period of extreme events. Changes at both the lower (e.g., reduction in precipitation leading to droughts) and the upper tails (e.g., high-intensity rainfall resulting in floods) of range of observed values can be expected. These changes may be in the following three ways: (1) a shift in the mean that will result in less low-magnitude events and more high-magnitude events; (2) an increase in standard deviation and thus variability that equates with more low- and high-magnitude events; and (3) a change in the shape of the distribution where low-magnitude events remain almost constant but high-magnitude events increase (IPCC, 2012).

Water and Biofuel Production

Biofuel has often been touted as a panacea for climate change. It is a vital part of the renewable energy family. Biofuels are gaseous or liquid transportation or heating fuels derived from biological sources, such as grains, sugar crops, starch, cellulosic materials, and organic waste (De Fraiture *et al.*, 2008). Biofuels include bioethanol and biodiesel. Bioethanol is produced by fermentation of sugar from plants, such as sugarcane, or from starch crops, such as corn, whereas biodiesel is made from vegetable oils or animal fats through a transesterification process.

Global biofuel production has been increasing steadily over the last decade – production rose from 16 billion liters in 2000 to more than 100 billion liters in 2011, and today biofuel provides approximately 3% of road transport fuel globally (on an energy basis) (International Energy Agency, 2013). The transportation sector is a major consumer of petroleum fuels, hence substituting biofuel for fossil fuel offers several advantages – it is a renewable energy source, provides energy security by lessening dependence on foreign oil supply, allows a fair trade balance by reducing the financial burden, is less polluting than petroleum fuel (less sulfur, carbon monoxide, and particulates), and reduces greenhouse gas (GHG) emissions; moreover, biofuel, usually used in a local industry, promotes rural economic and social development. These benefits have driven many countries to adopt policies that encourage local biofuel production (De Fraiture *et al.*, 2008; Demirbas, 2007).

In the United States, the Energy Independence and Security Act of 2007 mandated the annual production of 56.8 billion

Table 6 Major biofuel-producing countries, source of biofuel, and current and projected percentage of total water and irrigation water used for biofuel production

Country	*Biofuel (billion liters)*	*Main biofuel crop*	*% of total crop water used for biofuel*		*% of irrigation water used for biofuel*	
	2030		*2005*	*2030*	*2005*	*2030*

liter of ethanol from corn by 2015 and an additional 60.6 billion liter of biofuels from cellulosic crops by 2022 (Dominguez-Faus *et al.*, 2009). Around the world, Brazil already fuels a quarter of its ground transportation using ethanol derived from the fermentation of sugarcane sugar (Somerville, 2006). India, driven by environmental and rural development considerations, hopes that biofuels will account for at least 20% of its diesel and gasoline consumption by 2017. However, increasing biofuel production raises several concerns, among which exacerbating the stress on water demand, which is already a scarce resource in many countries, is a major one.

Biofuel production impacts water in many ways – enormous amount of water is required to irrigate feedstock crops, water is used during processing in biorefineries, and the quality of water bodies is affected by increased agricultural activities. These combined effects can be referred to as the water footprint of biofuel (Dominguez-Faus *et al.*, 2009). The water requirements for biofuel production depend on the type of feedstock used and on the geographic and climatic variables. Common crops that are used for biofuels production are the following: corn and soybeans (primarily in the United States), flaxseed and rapeseed (Europe), sugarcane (Brazil), and palm oil (Southeast Asia). The most water-intensive aspect of biofuel production is the water used in irrigating feedstock crops, whereas the water used by biorefineries is generally similar to that for oil refining (US Department of Energy, 2006). However, because water use in biorefineries is concentrated into a smaller area, the effects locally can be substantial. A biorefinery that produces 100 million gallons (378 541 m^3) of ethanol per year, for example, would use the equivalent water supply for a town of approximately 5000 people (National Research Council, 2008).

The water consumption of ethanol derived from corn grain is approximately 28 gallons per mile (66 l km^{-1}) (King and Webber, 2008). This is in strong contrast with the water consumption for conventional petroleum gasoline and diesel, which is 0.07–0.14 and 0.05–0.11 gallons per mile (0.16–0.33 and 0.12–0.26 l km^{-1}), respectively. Algae, another source of biofuel, is gaining much attention as, unlike corn or soybean, it does not compete with agricultural land for food crops and may produce 10 times more fuel per hectare. From a water requirement standpoint, however, it is not as efficient. Water consumption can vary anywhere between 3.15 and 3650 l of water for the amount of algal biofuel equivalent to 1 l of gasoline (National Research Council, 2012). The production of 39 billion liters a year, to meet a mere 5% of US transportation fuel needs, is currently unsustainable from a water requirement perspective. **Table 6** shows some major biofuel-producing countries, biofuel crop, and current and projected percentage of crop water used and percentage of irrigation water used for biofuel production. It is clear that production of biofuel will divert more and more of the water currently being used for food production, thus putting additional pressure on water allocation. More efficient irrigation techniques may reduce water consumption and mitigate the effect of biofuel production.

The production of biofuels not only affects water quantity but also affects water quality. Converting grassland to farmland requires both fertilizer and pesticide input and converting existing crops to biofuel will lead to an increase in nitrogen application (National Research Council, 2008). Water quality impacts of various crops can be compared based on fertilizers and pesticides application per unit of the net energy gain captured in a biofuel. Fertilizer requirement varies based on crop type. Corn requires the greatest amount of both fertilizer and pesticides. Between 24% and 36% of the nitrogen fertilizer applied to corn and soybean may be lost through runoff, sediment transport, tile drainage, and subsurface flow. This fraction may be a mere 5% during drought and as high as 80% during floods (Dominguez-Faus *et al.*, 2009). Thus, if proper farm practices and management plans are not implemented, the chemicals can negatively impact neighboring rivers and lakes and hence affect water quality.

Transboundary Water

According to the United Nations, there are 276 international rivers shared by two or more countries and 200 identified transboundary aquifers (UNESCO, 2013). Transboundary river basins cover 50% of the earth's surface (excluding Antarctica) and channels 60% of global streamflow (Biswas, 1999). Some 40% of the world's population lives within transboundary lake and river basins and two billion people depend on more than 300 transboundary aquifer systems (Du and Zhong, 2011).

Transboundary Waters and the Role of the State

Worldwide, countries have found more cost-effective methods to exploit water sources within their jurisdiction than to invest on water management strategies. The only remaining sources of water that can now be developed are mostly transboundary in nature (Biswas, 1999; Black and King, 2009).

Countries manage their shared watercourses considering their own national priorities, commonly overlooking water needs up- or downstream (Kreamer, 2012; Zeitoun, 2013). As this tendency grows, pressure over management enhancement and institutional governance at national and international level challenges the state accountability to cope with contemporary transboundary issues and future threats (Suhardiman and Giordano, 2012; Tarlock, 2000). Even though the role of state actors as the key players in international water affairs is not questionable, it is agreed that their role has been insufficient to understand actual challenges of transboundary water management. There is recognition of participation of nonstate networks, institutional soft power alliances on decision-making processes, and the existence of the scalar relationships and interactions between regional, national, subnational, and local influences (Sanchez and Kaiser, 2011; Zeitoun, 2013). The case of international organizations as key player in negotiators between coriparian river basins and the development of new governance scheme is well documented. The World Bank was mediator in the signing of the Indus River Basin treaty between India and Pakistan; the United Nations Environmental Program on the Zambesi River agreement between its riparians; and the United Nations Development Program (UNDP) over the Mekong River Basin agreement (Biswas, 2011b; Eckstein, 2011).

Water Interdependency: Conflict Versus Cooperation

Management of transboundary water is very complex, and so far only one-third of the transboundary river basins have a cooperative management framework. A transboundary basin can be a source of conflict and represent the potential for water wars or can represent an opportunity for cooperation among neighboring countries (Wolf *et al.*, 2005). Despite the fact that water scarcity may give rise to tension over shared water resources (Kreamer, 2012), international cooperation has been more often the rule than the exception (Giordano and Wolf, 2003; UNESCO, 2013). Black and King (2009) noted that between 1948 and 2008, 42 events related to transboundary river basins have led to hostile or military attacks, but 1743 events have resulted in verbal discussion; cultural, economic, technical, and scientific cooperation; and, in some cases, the signature of an international water treaty.

Even though it is clear that cooperative action may benefit transboundary neighbors, power asymmetry between parties has often been the impediment for effective cooperation over transboundary waters, which compromise water supplies and peaceful relations among parties (Ohlsson, 1995; Sanchez and Kaiser, 2011). Of the world´s 276 international basins, 166 do not have any treaty provisions covering them whatsoever. Only one-third of the multilateral basins are entirely covered by a treaty provision and most of those are limited to bilateral agreements (Biswas, 2008; Subramanian *et al.*, 2012). The United Nations International Convention on the Law of the Non-Navigational Uses of International Watercourses (1997) has only received 31 ratifications of the 35 required (McCaffrey, 2001; United Nations, 2005), which restricts this instrument from international commitment and subordinates it to existing bilateral and multilateral allocation treaties (McCaffrey, 2001; Tarlock, 2000).

Climate Change and Transboundary Water Management

Climate change will only exacerbate present water disputes between countries as water availability and quality changes (Khedun *et al.*, 2009; McCarthy *et al.*, 2007; Nordas and Gleditsch, 2005). Thus, recognizing climate change as one of the challenges for transboundary water management, the actual international legal framework (bilateral and multilateral agreements) will also be adversely affected. Generally, transboundary agreements have not been designed to cope with increased climate variability, as they are often restricted by rigid definitions of water allocation rather than percentages. The certainty of climate variability results in an increased pressure over alternative governance structures, potentially diminishing the legitimacy of weak international agreements (Suhardiman and Giordano, 2012). The declaration of the United Nations in 2013 as the International Year of Cooperation, which fosters states and other nonstate actors to promote actions to achieve cooperation in water related goals, aims the international need for new transboundary governance assessments.

Examples of Transboundary Water Management around the World

There are numerous examples of transboundary basins that represent valuable examples of the challenges pertaining to transboundary water management. Examples include the following:

The Jordan River basin

The classic case of the Jordan River basin is constantly referred to as the most securitized water region in the world (Biswas, 2011a; Wolf, 2001). The Jordan River is shared by Israel, Lebanon, Syria, Jordan, and the Palestinian Authority. Aside from being the most water-scarce region in the world, the Middle East represents a region where political and ideological conflict has been permanently ruling the relationships among its coriparians. For Israel, adequate access to water to support a growing population that has increased six times since 1949 (Gleick, 2000), and an agriculture highly dependent on irrigation, has been a constant concern over water resources allocation since the establishment of the nation (Giordano *et al.*, 2002; Wolf *et al.*, 2005). Likewise, high birth rates among Palestinians and Jordanians have put severe pressure on the already scarce water resources. In Gaza and the West Bank, the annual water availability per capita is below 100 m^3 (Israel less than 300 and Jordan approximately 100 m^3; Wolf *et al.*, 2005). With rising demand and water constraints, conflicts between Israel and its riparian neighbors have oscillated from verbal exchanges to hostile armed conflicts over proposed

water development projects (Wolf, 2000). However, even though historically Israel has been a permanent state of conflict (sometimes at war) with its Arab neighbors, there are examples in which water has constituted the singular bond among them. The 1990 Treaty of Peace between Israel and Jordan described substantial provisions, principles, and cooperative mechanisms over their shared waters. Alternatively, the 1995 Israeli–Palestinian Interim Agreement on the West Bank and Gaza Strip also entails cooperative mechanisms over the Jordan River basin. However, considering power asymmetry between Israel and Palestine, Israel tends to dominate the water situation in the region.

The Mekong River basin

The Mekong River basin is shared by six countries: China, Myanmar, Laos, Thailand, Cambodia, and Vietnam. The magnitude of its challenging interdependency relies mostly on the fact that it is the major water supply in Southeast Asia, source of food and transport to more than 70 million people and home of the most diverse inland fisheries in the world (Black and King, 2009; Houba *et al.*, 2012; Sneddon and Fox, 2006). To cope with the challenges of population growth, expanding irrigation, and hydropower generation, the Mekong River Commission was formed in 1995 between Cambodia, Laos, Thailand, and Vietnam, with the godfathering effort of the UNDP (Biswas, 1999). Even though this Commission highlights the effort toward a cooperation scheme among coriparians to avoid water conflict, the fact that China, the most powerful country in the basin located upstream of the river, is not a signatory of the agreement. In fact, China voted against the resolution to establish the 1997 Convention on the Law of Non-Navigational Uses of International Watercourses (Biswas, 2011a). The expectations regarding the improvement of sustainable water use in the Mekong basin are not high, and the potential for conflict threaten the stability of the region (Biswas, 2011a; Houba *et al.*, 2012). China, pressured by rapid population growth and water for all uses, has already started the construction of series of dams on the upper reaches without consultation with the Commission, thus threatening water supply for downstream users (Black and King, 2009; Sneddon and Fox, 2006). The magnitude of power asymmetry between China and its coriparians does not offer high possibilities to avoid Chinese priorities to rule the basin's water agenda, despite the negotiation and mediation efforts of the UNDP.

The Rio Grande/Río Bravo Del Norte river basin

The Rio Grande river basin, shared by Mexico and the United States, is the most water-stressed region in the continent (UNESCO, 2013). Population growth and extensive and intensive water use for irrigation, combined with drought persistence as climate change imposes new precipitation regimes in the region, are also identified as common challenges (Castro-Ruiz and Gonzalez-Avila, 2012). However, the particularity of this case relies in the fact that despite power asymmetry between the two riparian countries, Mexico and the United States have cooperated intensively and reasonably since the beginning of the 1900s to efficiently and equitably share the waters of the Colorado and the Rio Grande basins (Mumme, 2003; Sanchez-Munguia, 2011). Nevertheless, since the 1980s and more permanently since the 1990s, drought conditions and climate variability have exposed the limitations of the 1944 US–Mexico Treaty. Industrialization and immigration to the region incentivized by the North America Free Trade Agreement of 1994 have accelerated population growth (quadrupled since 1945) and overallocation of water rights in the region has reached its limits (Biswas, 2011b). The treaty (as most treaties around the world) does not contain provisions on water allocation considering climate variability scenarios (Hurd, 2012) and the treaty provision in which timing of water deliveries (5-year cycles) from Mexican tributaries to the United States (Texas) facing a rather constant drought period, do not seem enough to satisfy current water demands (Castro-Ruiz and Gonzalez-Avila, 2012). Further, transboundary groundwater, which is primary source of water for approximately 12 million people, is not even considered in the 1944 treaty (Eckstein, 2011; Mumme, 2000; Sanchez, 2006). Climatologic, hydrologic, but more importantly, institutional and legal challenges govern the US–Mexican conflict/cooperation relationship over shared waters of the Rio Grande and expose the need to evaluate the adequacy of the 1944 Treaty under actual and future conditions (Mumme, 2003; Mumme, 2000).

Conclusions

Providing water to growing areas with limited supplies is a daunting challenge. Climate change further exacerbates water scarcity challenges, especially region that are expected to receive less rainfall (Khedun and Singh, 2013a). Although distributional scarcity is a new reality, there is still time to adopt a new paradigm based on 'sustainable' water management practices. Practices must shift from supply development to demand and supply management incorporating more efficient agricultural irrigation, conservation, reuse, new technologies for water purification, smart improvements to infrastructure, water planning integrating economic, equitable use, and environmental factors with real participation by the widest realm of water users and communities (Brooks, 2005; Kaiser, 1996; Kaiser and Skillern, 2001; Khedun and Singh, 2013b; Wolf and Gleick, 2002). Like most paradigm shifts the practice of 'sustainable water management' will move slowly until accelerated by drought, real climate change, and long-term water scarcity.

Zoonotic Helminths of Livestock

AR Moorhead, University of Georgia, Athens, GA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Cestode Hermaphroditic flatworms that are segmented and are commonly known as 'tapeworms.'
Definitive host The host in which sexual reproduction occurs.
Helminth Worms, including roundworms (nematodes) and flatworms (trematodes and cestodes).
Intermediate host A host in which a stage of the parasite grows and develops, but no sexual reproduction occurs.
Nematode Roundworms that have a cylindrical shape and can range in size from microscopic to several meters in length.
Paratenic host A transport host in which a stage of the parasite does not grow and develop, and no sexual reproduction occurs. It is used to bridge an ecological gap.
Trematode Hermaphroditic flatworms that are unsegmented and are commonly known as 'flukes.'

Introduction

The term parasite is derived from the Latin term *parasitus*, which literally means one who dines at another's table. In veterinary medicine, parasites are typically defined as eukaryotic organisms that are single- or multicelled and live within or on the host. Major parasites can be helminths, protozoa, or ectoparasites, which are arthropods, primarily insects or arachnids. Leeches and pentastomes are two other classes of parasites that are less commonly encountered. Parasites from each of these classes can infect humans (Bowman, 2009). The human can be the definitive host, that is the host in which sexual reproduction occurs, or can be an intermediate host, which is a host in which a stage of the parasite grows and develops but no sexual reproduction occurs. In many situations, humans are not the intended intermediate host, but rather are accidently infected. This is particularly true in the case of parasitic zoonoses.

Zoonotic transmission of parasites can be derived from either agricultural or food animals (i.e., sheep, goat, cattle, swine, and poultry) or companion animals (i.e., dogs and cats). There are some common protozoal diseases that affect both livestock and companion animals, most notably toxoplasmosis and cryptosporidiosis (Bowman, 2009). Although protozoal diseases are quite important, helminth zoonotic diseases will be the focus of this article, specifically parasitic zoonoses derived from domesticated agricultural animals. There are a great number of parasites that deserve inclusion in this article; however, examples primarily from swine are detailed. The physiology of pigs is relatively close to that of humans when compared to other domestic animals, which most likely explains why quite a few parasites go between swine and humans. Many of the basic principles from the parasites described below can be applied to other zoonotic parasites.

The Basics of Helminth Life Cycles

The three major types of helminths of zoonotic importance are the nematodes, trematodes, and the cestodes. Knowledge of the parasite life cycle is absolutely imperative if one is to appropriately treat, prevent, and diagnose parasitic diseases. Although life cycles are extremely varied in the exact details, the general features of the life cycles are quite similar.

Nematodes

Nematodes are commonly known as roundworms due to their cylindrical shape and can range in size from microscopic to several meters in length (Gibbons, 2002). They are pseudocoelomates, which means that although they have a complete digestive tract, they do not have a complete body cavity or coelom. Literally, they are a tube within a tube (Gibbons, 2002). They are dioecious, and with rare exceptions, males and females must mate to produce offspring (Bowman, 2009). During their development to adulthood, nematodes will molt four times to the juvenile adult stage, which is also known as the L5 or fifth-stage larva. This juvenile adult will then mature into an adult without molting. Mature males and females will then mate. Females will then typically shed one of the following: (1) live offspring, (2) eggs containing fully developed

 doi:10.1016/B978-0-444-52512-3.00191-1

larvae, or (3) eggs containing an undeveloped embryo. These stages will then follow one of the following strategies in order to gain entrance into the definitive host: (1) ingestion by an arthropod intermediate host through the taking of a blood meal from the definitive host, (2) subsequent ingestion of an arthropod or mollusk intermediate host or larvae shed in the feces, (3) ingestion of a larvated or nonlarvated egg, (4) ingestion of a paratenic (transport) or intermediate host that contains larvae in their musculature or organs, or (5) penetration of the skin by the larvae (Lee, 2002). Although this list does not include all life strategies employed by nematodes, it does include the majority.

With very few exceptions, parasitic nematodes are internal parasites. Once inside the host, the infectious stages normally migrate in complicated pathways through a variety of organs. These migrations vary by family, and even genus and species. The end result of these migrations is that a male and female worm will be present in a location that will allow mating and the subsequent shedding of either eggs or larvae. These infectious stages will then infect an intermediate or definitive host as described by one of the strategies described above.

Trematodes

The phylum Platyhelminthes contains the class Trematoda, more commonly known as the trematodes. Most of the common zoonotic trematodes are digenetic, which means these worms require a minimum of two hosts to develop into the adult stage (Nithiuthai *et al.*, 2004). Asexual and sexual reproduction normally occur in an invertebrate and vertebrate host, respectively (Roberts *et al.*, 2013a). Trematodes are primarily hermaphroditic with the family Schistosomidae being a notable exception (Mone and Boissier, 2004). Adult worms live in a variety of locations in the definitive host, including the lungs, liver, and stomach (Bowman, 2009). Regardless of location, operculated eggs are shed in the feces of the definitive host. After a designated time period, which is dependent on temperature, oxygen tension, and pH, the eggs will develop into a miracidium. The miracidium is a ciliated free-living organism, which upon hatching from the egg, enters a mollusk – the intermediate host (Roberts *et al.*, 2013e). The hatching process can occur in water or after ingestion by the requisite intermediate host. In the case of certain species such as *Fasciola hepatica*, light facilitates hatching (Wilson, 1968).

Once inside the intermediate host, usually a snail, the miracidium undergoes a complex series of morphological changes to the saclike sporocyst. Inside this sporocyst, other sporocysts, known as daughter sporocysts, may develop. Alternatively, another intermediate stage, the redia or germinal sac, may develop. Rediae normally exit the sporocyst in a dramatic manner, rupturing the membrane, after which they begin a wandering migration around the host. Rediae can then either develop into daughter rediae or into the next stage, which is the cercaria. The cercariae leave the host and can infect a definitive host in the case of the family Schistosomidae. In other trematodes, the cercariae will either infect a second intermediate host, where they may enter a dormant stage known as the metacercariae (Roberts *et al.*, 2013e). Alternatively, the cercariae of some trematodes, such as the family Fasciolidae, will remain in the environment where they encyst as metacercariae (Olsen, 1947). The life cycle is completed when the definitive host ingests either the second intermediate host containing the metacercariae or the encysted metacercariae in the external environment. As with nematodes, the trematodes undergo complex migrations within the host, after which they arrive at the designated tissue (Nithiuthai *et al.*, 2004; Roberts *et al.*, 2013e). The life cycle and biology described above is what would be considered a classic trematode life cycle. As with all organisms, there are notable exceptions.

Cestodes

There are two major classes of cestodes: the psuedophyllideans and cyclophyllideans, also known as the true tapeworms (Raether and Hänel, 2003). This article focuses mainly on cyclophyllidean tapeworms.

Almost exclusively, adult cestodes live within the gastrointestinal tract of the definitive host, and are divided into hermaphroditic segments called proglottids. The cestodes discussed below are polyzoic – that is they possess multiple proglottids. These proglottids are uniform in structure, but increase in size proximally to distally as the worm grows. The worms will attach to the wall of the intestine via suckers or hooks, which are on the most proximal segment, or scolex, of the tapeworm. It is from the 'neck' area of the scolex that proglottids are formed by a process known as strobilation. Eggs are produced in the proglottids, and depending on the species, the egg-containing proglottids or eggs are shed in the feces (Bowman, 2009; Roberts *et al.*, 2013d). As compared to some nematode species and trematodes, these eggs are directly infective. In other words, these eggs require no time for development outside the host, in order to become infective to the intermediate host (Nithiuthai *et al.*, 2004). After ingestion of the egg, the embryophore or hexacanth embryo hatches from the egg (Bowman, 2009; Roberts *et al.*, 2013d). After hatching, the hexacanth embryo migrates to a locale in the host that was designated by evolution tens of thousands of years ago. In its final location within the intermediate host, the scolex will develop into what can be described as a capsular structure or cyst, whose morphology varies by parasite species. The stages within the intermediate host are known as metacestodes, and will normally contain a scolex (Roberts *et al.*, 2013d). These intermediate stages are so distinct from the adult worms that it was previously thought that they were a separate species of parasite versus an intermediate stage within an intermediate host. For the parasites discussed, the parasites are transmitted from the intermediate host to the definitive host by means of a predator–prey relationship. Once inside the host, the scolices will attach inside the intestine and begin to grow.

Zoonotic Nematodes

There are many zoonotic nematodes, but some of the most well-known ones (such as the canine roundworm *Toxocara*

canis and the canine hookworm *Ancylostoma caninum*) are transmitted from domesticated canines to humans. However, there are some excellent examples of zoonotic nematodes that are transmitted from domesticated food animals to humans. Two of the most well-known species, the pig roundworms *Ascaris suum* and *Trichinella spiralis*, are discussed below.

Ascaris suum

Ascaris suum is the large roundworm of the pig (*Sus scrofa*) and can easily infect humans. This should come as no surprise, because previously *A. suum* and the human roundworm, *Ascaris lumbricoides*, have been considered the same species (Rogers, 1956). This debate is ongoing with some more recent paleoparasitological and genetic evidence supporting the assertion that the two species are indeed one (Leles *et al.*, 2012). Regardless of the species debate, one would not want to ingest the infectious eggs of *A. suum*, which is what happened when Eric Kranz put *Ascaris* eggs in the food of his roommates when he was asked to leave the premises for failure to pay his share of the rent (Carus, 2001). The roommates developed a rather nasty infection as a result (Phills *et al.*, 1972). The bottom line is that cross-infection can result, and precautions should be taken to prevent human infection with *A. suum* (Crewe and Smith, 1971).

Biology

Ascaris suum is currently classified in the infraorder Ascaridiomorpha, family Ascarididae (Roberts *et al.*, 2013b). The ascarids, as they are commonly known, tend to have complex life cycles that can involve relatively complicated migrations through the intermediate/paratenic host or the definitive host (Lee, 2002; Bowman, 2009). For *A. suum*, and its human counterpart, *A. lumbricoides*, the life cycle occurs almost exclusively in the definitive host, with the exception that some larval development inside the eggs occurs while the eggs are in the environment (Dold and Holland, 2011). Adult worms inhabit the small intestine and can grow to a length of 31 and 49 cm, for males and females, respectively (Roberts *et al.*, 2013b). The females are prodigious egg layers, producing up to 200 000 eggs a day, which are shed into the environment in the feces (Sinniah, 1982). This level of production practically ensures that another host will become infected. The outside of the eggs contain a sticky saccharide coating, which surrounds an extremely resilient membrane (Nansen and Roepstorff, 1999; Quiles *et al.*, 2006). The result of this combination is an egg that is both extremely difficult to kill, as well as remove, since the eggs survive quite well in a variety of temperatures and solutions (O'Donnell *et al.*, 1984). These eggs are shed unembryonated, and are not immediately infective. Depending on the temperature, eggs will be infective 2–4 weeks after being excreted into the environment. At this point, they contain the infective third-stage larvae (L3) (Geenen *et al.*, 1999). Eggs can survive for quite some time, although extreme heat and prolonged exposure to sunlight will kill the larvae (Gaasenbeek and Borgsteede, 1998; Quiles *et al.*, 2006). Once ingested by the definitive host, or a suitable paratenic host, these eggs will hatch and the L3 will be released into the intestine (Dold and Holland, 2011). After entering the intestine, the L3 will penetrate the intestine and travel via the blood to the liver, after which the larvae will migrate via the blood vessels to the lungs (Murrell *et al.*, 1997; Roepstorff *et al.*, 1997). Once in the lungs, the larvae will literally burst out of the alveoli. After entering the alveolus proper, the L3 will then travel up the trachea in a process known as tracheal migration. After rising up the trachea, the larvae are swallowed, and travel to the intestine, where they will mature to adults (Roepstorff *et al.*, 1997). This process takes approximately 60–65 days from ingestion of egg to maturation of the adult (Roberts *et al.*, 2013a).

Epidemiology

As mentioned above, the females are prodigious egg layers, producing large numbers of environmentally resistant eggs (Sinniah, 1982). In commercial swine operations, most of the transmission occurs between the sow and the piglets in the farrowing house. The sticky eggs that are in the surroundings and adhered to the sow are inevitably ingested in large numbers by piglets (Nansen and Roepstorff, 1999). Transmission can also occur among other age groups as well, since there is little evidence of age-related immunity to the parasite (Eriksen *et al.*, 1992). In areas where pigs are not raised in confinement, the infective eggs can be present in the soil. Animals can ingest these eggs as they root and forage for food (Roepstorff and Murrell, 1997). Also, pigs that are reared outdoors can become infected by ingestion of paratenic hosts. It is important to remember that pigs are omnivores, not herbivores, and do not hesitate to eat rodents, which could be harboring encysted or migrating *A. suum* L3. This is potentially a means of transmission in underdeveloped countries.

Clinical signs/pathology

Clinical signs and the associated pathology can vary depending on the number of worms that are present, as well as the stage of the parasite. A few adult worms will not result in any observable clinical signs. Typical signs can include diarrhea and a failure to gain weight (Stewart and Hale, 1988). However, a large number of worms can result in intestinal blockage. In extremely severe cases, worms have migrated into the bile duct, although this is a rare occurrence (Bowman, 2009).

Migrating larvae can also result in clinical signs (Spindler, 1947). As the larvae migrate through the lungs, they release antigen. The body responds to this insult with a myriad of inflammatory cells. The inflammation eventually heals resulting in lung fibrosis (Bowman, 2009). This makes it difficult for the animals to breathe, resulting in a condition commonly known as 'thumps' (Spindler, 1947). The migrating larvae can also cause damage to the liver, through which they migrate prior to migration through the lungs. After the initial damage, the liver, like the lungs, responds with an initial inflammatory response, followed by fibrosis. These fibrotic spots are known as 'milk spots' and can result in the condemnation of the liver at slaughter (Sanchez-Vazquez *et al.*, 2012). Other than the condemnation at slaughter, there are no major clinical manifestations associated with migration of the larvae through the liver.

Control/prevention

If the egg-contaminated feces is removed before the development of the infectious L3 within the egg, then theoretically, transmission from one pig to another could be prevented. However, this solution is far from practical, and not a realistic possibility. Although this control measure is feasible for control of dog ascarid infections, it is not in any way possible for control of *A. suum*. In both indoor- and outdoor-reared pigs, the feces can be spread throughout a pen, making it difficult to remove the feces immediately after contamination. Periodically steam-cleaning pens will remove and kill the larvae inside the infective eggs. Since eggs are not immediately infective, cleaning the pen or area every few weeks should decrease transmission (Bowman, 2009). Also, preventing access of pigs to paratenic hosts, with rodents being the most likely, should also decrease transmission.

Zoonotic potential

As stated above, the life cycle of *A. suum* in the human host is almost identical to that of the human roundworm, *A. lumbricoides* (Rogers, 1956). In fact, there has been some debate about whether the two are the same parasites (Leles *et al.*, 2012). Genetically, there have been some studies that seem to indicate that there is some difference, although this debate is still ongoing (Anderson *et al.*, 1993; Dold and Holland, 2011; Leles *et al.*, 2012). Regardless of the scientific debate, *A. suum* can mature in humans, and causes almost identical signs as it does in pigs. Mild infections are well tolerated, whereas heavy infections can result in the signs described above (Crewe and Smith, 1971; Carus, 2001; Dold and Holland, 2011).

Trichinella spiralis

Trichinella spiralis is described as the worm that would be a virus, due to its unique biology (Despommier, 1990). At one point during its life cycle it will inhabit and take over the host cell (Wu *et al.*, 2013). Trichinellosis also has an important place in history – the reason that certain religions do not consume pork, because it is an important source of infection (Murrell and Pozio, 2011). It has been debated that Amadeus Mozart died as a result of *Trichinella*-infected pork (Dawson, 2010). Although some argue he died of the disease, others argue that the reported signs and symptoms would not meet the clinical definition of trichinosis. One key point in the debate is that Mozart would not have been able to compose his famous *Requiem* mass due to the extreme muscle pain, or myalgia, which can be present with the disease (Dupouy-Camet, 2002). Regardless of whether trichinosis killed Mozart, the importance of *Trichinella* as a zoonosis cannot be overstated. It also has one of the simplest solutions for prevention of transmission, which is not ingesting undercooked meat. For this disease, the bottom line is to cook meat to the appropriate temperature, till it is free from *Trichinella*.

Biology

Trichinella spp. are nematodes in the family Trichinellidae. There have been debates about the speciation of *Trichinella*, but it is agreed the primary species is *T. spiralis*, with *T. nativa* playing an important role in transmission in Arctic areas (Murrell *et al.*, 2000; Larrat *et al.*, 2012). *Trichinella pseudospiralis* also plays a role in infection, but is of limited importance when compared to *T. spiralis* (Murrell *et al.*, 2000). Further discussion focuses primarily on *T. spiralis*.

The host range of *T. spiralis* is quite large, as many mammals can become infected with the parasite. However, the major point to remember about the *T. spiralis* life cycle is that transmission is based on carnivorism, so herbivores rarely become infected (Bruckner, 1999). The life cycle is divided into two separate stages: enteral and parenteral cycles.

The enteral stage

Animals become infected by eating the infected muscle of other animals (Bruckner, 1999; Roberts *et al.*, 2013c). The first-stage larvae are encysted in the muscle cells. On ingestion by a mammalian host, the larvae are released from the muscle during digestion in the stomach (Bowman, 2009). The larvae then enter the small intestine, where they travel in between the villous crypts in the small intestine. In 30–32 h following ingestion, the larvae become sexually mature adults, which then release newborn larvae within 5 days (Gardiner, 1976; Bowman, 2009). Perhaps the most fascinating aspect of the *T. spiralis* life cycle is that every animal can serve as a definitive host. One must remember that a definitive host is one in which sexual reproduction of the parasites can occur. Because the worms mature and reproduce in each infected host, each infected animal, by definition, is a definitive host.

Parenteral stage

After birth the newborn larvae penetrate the intestine and then enter the lymphatics, where they migrate via the bloodstream to the musculature (Ali Khan, 1966). Once they reach the muscle, the larvae then literally invade the cell. Hence the description of *T. spiralis* as the worm that would be a virus, since viruses also invade cells (Despommier, 1990). During a 2- to 3-week period, the larva changes the cell into what is known as a 'nurse cell' (Bowman, 2009). Many physiologic changes occur in the cell, as the parasite adapts the cell for its needs (Despommier, 1990). At this point in the infection, the larva can remain alive within the cell for literally years, without causing a significant immune reaction or pathology (Dabrowska, 2013; Roberts *et al.*, 2013a). However, large numbers of nurse cells within a particular muscle group can cause clinical signs and pathology (see Section Clinical signs/pathology of animals). Once the muscle is ingested by a suitable host, the larvae are released from the muscle and the life cycle is completed (Roberts *et al.*, 2013c).

Epidemiology

Some of the greatest stories about public health involve trichinellosis, the condition that occurs when one is infected by *Trichinella* spp. Trichinellosis has historically been associated with pigs. Typically, pigs are infected by cannibalizing other pigs or ingesting rats (Hanbury *et al.*, 1986; Leiby *et al.*, 1990). Pigs also become infected when they are fed 'garbage.' Garbage in this case is defined as undercooked meat scraps. Pigs will ravenously consume this mixture, because of their tendency to consume a variety of food, due to their ominivorous nature. Although commercial swine operations typically do not engage in the practice of garbage feeding, many smaller farms do

(Zimmerman, 1968). When humans ingest the meat of infected pigs that has not been properly cooked, they become infected.

Whereas pigs are domestic animals that are considered the most likely source of infection for humans, other domestic animals that cause infection also have been documented. Certainly consumption of undercooked infected meat of domestic carnivores, such as dogs or cats, could result in human infection. Counterintuitive to the normal infection paradigm for trichinosis, infection of herbivores has been reported (Moorhead *et al.*, 1999). One of the most famous cases involved an outbreak among humans in France, due to ingestion of infected horse meat. Since horses are herbivores, one would logically assume they should not be infected with *T. spiralis*. It is hypothesized that an infected rat actually fell into the grinder when the horse feed was being produced. The larvae would have been in the nurse cells at this point, and would have become activated on exposure to the gastric fluids in the horse's stomach. The horse would have then become infected (Laurichesse *et al.*, 1997). This case drives home an important point regarding trichinellosis. While carnivores and omnivores are more likely to be infected than herbivores with the parasite, it is due to a difference in consumption habits, not due to physiology. Remember, any mammal can become infected with *Trichinella* spp.

The last point of discussion is regarding trichinellosis epidemiology, which is unrelated to agriculture. In the United States, the primary means of infection for trichinellosis is actually ingestion of undercooked wildlife, not infected commercially raised pork (Moorhead *et al.*, 1999). Currently, there is a USDA program in place to certify pork *Trichinella*-free, thus reducing the need to cook the meat at as high temperatures as previously recommended. Pork from wild pigs, and other carnivores, such as bear and cougar, needs to be cooked thoroughly (Dworkin *et al.*, 1996; Kennedy *et al.*, 2009). Also, meat from herbivores, such as deer needs to be cooked thoroughly. As was described for the case above involving the ingestion of horse meat, deer meat can be contaminated if it is ground using a grinder that was previously used to grind contaminated boar, or other wild animal (Moorhead *et al.*, 1999). The bottom line is that if one is unsure of the source of the pork or wildlife, then one should assume that it is infected with *T. spiralis* and cook it using the appropriate precautions (Pozio, 2001).

Clinical signs/pathology of animals

Signs associated with human infection are much better documented than in animals (Murrell and Pozio, 2011). The clinical signs in animals typically associated with infection may include diarrhea during the enteral phase. Invasion of the muscle may or may not result in clinical signs, such as myalgia and fever. It must be noted that if the diaphragm is one of the muscles that is heavily infected, dyspnea (difficulty breathing) and even death could result. On histologic examination of infected muscle, microscopic cysts representing the nurse cells may be observed (Bowman, 2009).

Control/prevention

Control of trichinosis can be achieved at two points: (1) preventing ingestion of contaminated feedstuffs or meat by animals and (2) preventing ingestion of contaminated meat by humans (Bruckner, 1999; Pozio, 2001).

For prevention in animals, focus shall be on prevention in swine. Prevention in animals is theoretically simple, but practically difficult to achieve. First, one needs to prevent cannibalism between pigs. This can obviously be difficult when animals are grouped housed. Also, removing any dead animals as soon as possible after discovery is a prudent measure (Hanbury *et al.*, 1986). The second is to prevent access of pigs to infected rodents. Again, this is a difficult proposition. In commercial operations, standard biosecurity and rodent control measures should be employed (Leiby *et al.*, 1990). In outdoor operations, this will be near impossible. Finally, cooking garbage (i.e., meat scraps) is paramount to preventing infection (Zimmerman, 1968; Leiby *et al.*, 1990).

For humans, preventing ingestion of *Trichinella* spp. can be accomplished by two ways: (1) prevent infected animals from entering distribution channels and (2) eliminate the infective larvae in the meat. To prevent infected meat from entering the human food chain, the meat needs to be screened in order to confirm that it is not infected. In Europe, this is accomplished through use of what are known as trichinoscopes. Slices of diaphragms, where encysted *T. spiralis* larvae in nurse cells can be present in high numbers, are placed on a slide and visually examined (Bowman, 2009). The meat from negative animals, or more appropriately those where no parasites are observed, is allowed to enter the food chain, whereas those from positive animals is discarded. This is a somewhat outdated method, and certainly animals with a low larval burden might not be detected. The other method is by use of enzyme-linked immunosorbent assay (ELISA), which is used much more frequently today (Gajadhar *et al.*, 2009).

In the United States, routine screening methods are not used for pork, much less wild game. Instead proper cooking or freezing of the meat is relied on. Meat must be uniformly cooked to an internal temperature of 77 °C, or alternatively frozen for several weeks. Curing, smoking, or other preparations that do not meet the criteria will not eliminate the larvae (Gajadhar *et al.*, 2009). Furthermore, freezing will not work on the cold-adapted *Trichinella* species, *T. nativa*. Therefore, while ingesting arctic game, such as polar bear, one must make sure to cook rather than freeze the meat (Skirnisson *et al.*, 2010).

Zoonotic potential

As one can see, the zoonotic potential for *Trichinella* spp. is quite large. Over the years, there have been multiple outbreaks in multiple countries (Murrell and Pozio, 2011). Normally, when humans are infected, there could be some diarrhea associated with the enteral phase. This can be mild to severe depending on the parasite load. Two to three weeks post-infection, myalgia may be associated with the parenteral phase (El-Beshbishi *et al.*, 2012). Also, periorbital edema can occur. Normally, this is the extent of the disease. However, if there is a large worm burden, and there are a large number of larvae localized in the heart or diaphragm, then significant problems can occur, either due to inhibition of cardiac function, or a result of respiratory distress secondary to a loss of diaphragm function. In summary, there can be minor morbidity

associated with trichinosis in many cases. In the few cases where there are severe clinical signs, mortality can result (Murrell and Pozio, 2011).

Zoonotic Cestodes

There are quite a few zoonotic cestodes of significance. Arguably, the most significant of these are cyclophyllidean tapeworms in the family Taeniidae (Raether and Hänel, 2003). Two of the most interesting tapeworms are the *Taenia saginatta* and *Taenia solium*. Both use man as the definitive host, and use cows and pigs as intermediate hosts, respectively (Bowman, 2009). As with many tapeworms, the pathology to the definitive host is minimal. For both these species, the pathology to the intermediate host is also minimal. However, there is a unique aspect to the biology of *T. solium*, which makes this tapeworm a very important zoonosis, especially in developing countries (Raether and Hänel, 2003).

Taenia saginata

Biology

As stated above, *T. saginata* uses man as the definitive host. Humans become infected with *T. saginata* when cow muscle containing the cysticercus is ingested (Bowman, 2009). The cysticercus is the intermediate form of the tapeworm, and is best described as small fluid-filled sacs (up to 10 mm in diameter) that contain an invaginated scolex. These cysticerci, which are infective within 2 months, are located within the fibers of striated muscles (Roberts *et al.*, 2013a). When the beef is ingested by the definitive host, man, the cysticercus becomes activated by the digestive juices and devaginates. These scolices then attach to the small intestine after which time the tapeworm will start to elongate as the number of proglottids increases (Bowman, 2009; Roberts *et al.*, 2013d). As stated above, tapeworms are hermaphroditic. Although they can mate with other proglottids of the same tapeworm, they prefer to mate with proglottids of different tapeworms. The proglottids are gravid after 2–12 weeks, and the tapeworm normally reach a length of 3–5 m, but some of over 20 m in length have been documented (Roberts *et al.*, 2013a).

With some tapeworms, the eggs (which are technically oncospheres because of a lack of a defined shell) are shed in the feces, whereas in other species (Raether and Hänel, 2003), the eggs are contained within the proglottid proper. In the latter instance, and in the case of *Taenia* spp., when the proglottid is damaged, eggs are released in the feces. When these eggs are ingested by cattle, the eggs will hatch in the intestine, and the scolex will devaginate, and then migrate through the mucosal wall of the intestine. They will then be carried by the bloodstream where they will lodge in the striated muscle, and form a cysticercus. When a human ingests a cysticercus, the life cycle is complete (Bowman, 2009; Roberts *et al.*, 2013a).

Epidemiology

Taeniasis, as a result of *T. saginatta* is rare in the United States and is more prevalent in Latin America, Africa, and Eastern Europe/Russia (Raether and Hänel, 2003; Ito *et al.*, 2004). Typically transmission occurs in areas where cattle are concentrated, such as feedlots. People will either defecate in the area of the cattle or proglottids will fall out of people's pants. Cattle will then ingest the eggs and the life cycle is complete (Bowman, 2009).

Clinical signs/pathology of animals

There are minimal signs in both the animal intermediate host and the human definitive host. The cysticerci are apparent on eating the meat. Also, the cysticerci or 'beef measles' can be seen during meat processing and can result in condemnation of the carcass (Bowman, 2009). Infestations rarely cause clinical signs in humans with the exception of heavy infections, which could cause gastrointestinal signs including upset stomach .

Control/prevention

Control measures include not ingesting 'measly beef,' containing cysticerci. Alternatively, if the meat is thoroughly cooked then transmission will not occur, as the cysticerci will be killed by cooking to an internal temperature of 56 °C. Humans who are infected should be treated and not allowed around areas such as feedlots and pastures. Cattle will often eat human feces, so prevention of pasture contamination is absolutely essential (Silva and Costa-Cruz, 2010; Roberts *et al.*, 2013a).

Zoonotic potential

The zoonotic potential is self-explanatory as humans are the definitive host.

Taenia solium

Biology

The life cycle of *T. solium* is quite similar to *T. saginata* except that the pig is the intermediate host instead of the cow. As with *T. saginata*, man is the definitive host for *T. solium*. Also similar to *T. saginata*, people become infected when they ingest pork muscle containing, the cysticerci. After the requisite growth, an adult *T. solium* is present in the intestine of the human. However, there is one very crucial difference in this life cycle and it is a potentially deadly one. Man can not only serve as the definitive host, but can also serve as the intermediate host. When this situation occurs, humans do develop cysticerci. Normally, these cysticerci do not cause overt disease. However, when cysticerci occur in the brain, a condition known as neurocysticercosis can result and the parasite can incapacitate or kill the intermediate host (Raether and Hänel, 2003). There are differing sizes of cysticerci, and the relatively large ones could be 20 cm in diameter. When an object of this size is in the brain the result can be catastrophic, with clinical signs ranging from impaired balance to paralysis (Roberts *et al.*, 2013d). This is why prevention of this disease is paramount.

It is important to remember the primary means by which humans develop neurocysticercosis is to ingest an egg, which is shed by another human. Once ingested, this egg undergoes the same migration pathway as in the pig intermediate host, exiting the intestine and accessing the bloodstream. Via the

bloodstream, these eggs can travel to a variety of locations, including the brain. This is a dead-end pathway for the life cycle. Formation of the cysticercus is the same in the pig as in the cow with *T. saginata* (Roberts *et al.*, 2013d).

Epidemiology

Taeniasis, as a result of *T. solium*, like *T. saginata*, is not that common in the US population except among immigrants from Latin America, where it is prevalent. Also, human *T. solium* infection occurs in India, Asia, Eastern Europe, and sub-Saharan Africa. Typically, transmission occurs in areas that are underdeveloped and where people ingest undercooked pork, which results in infection with adult tapeworms (Raether and Hänel, 2003; Del Brutto, 2012).

For neurocysticercosis, the epidemiology is a bit more complex. Typically, infected humans are in more underdeveloped areas, where sanitation may not be a priority, or sanitation measures are unavailable. If handwashing cannot be accomplished easily for either of these reasons, then the possibility exists that feces containing infective eggs may still be present underneath the fingernails or on the hands. Consequently, food for human consumption may become contaminated during preparation. If these eggs are then ingested, then the humans become the intermediate host (Del Brutto, 2012).

The general public was introduced to the disease neurocysticercosis in Robert Desowitz's book, *New Guinea Tapeworms and Jewish Grandmothers* (1981). However, one of the most famous outbreaks occurred in the early 1990s in an Orthodox Jewish community in New York City. Briefly, multiple members of the Orthodox Jewish community developed neurocysticercosis. The members of this community consumed no pork for religious reasons, and therefore most likely would not be infected with adult tapeworms. The source of outbreak was traced back to an active infection with *T. solium* in a Latin American housekeeper who had recently entered the United States. Food for consumption become contaminated with *T. solium* eggs during preparation, and as a result, the members of the community became infected. This case reinforces the necessity of handwashing in prevention of *T. solium* infection (Schantz *et al.*, 1992).

Clinical signs/pathology of animals

There are minimal signs in the swine intermediate host. Similar to *T. saginata*, the cysticerci are apparent on eating the meat, and can also be observed during meat processing (Roberts *et al.*, 2013d).

As compared to *T. saginata*, and as stated above, infections can be deadly in humans when we are the intermediate host. Neurocysticercosis can result in cavitated lesions in the brain, which causes seizures, or other neurological signs and symptoms in the host. The disease can progress to coma and death. Treatment with praziquantel will kill cysts, however, the death of the cyst can result in inflammation, which will either cause or further exacerbate neurologic signs and symptoms. Therefore, praziquantel must be used with caution in cases of active cysticercosis (Del Brutto, 2012). As with *T. saginata*, infections with adult *T. solium* rarely cause disease, with the exception of the occasional gastrointestinal signs (Roberts *et al.*, 2013d).

Control/prevention

Control measures include not ingesting pork containing cysticerci. This includes condemning carcasses containing cysticerci at slaughter. Alternatively, if the pork is thoroughly cooked then transmission will not occur, as the cysticerci will be killed by cooking to proper temperatures. Infected humans should be very careful not to contaminate foodstuffs. Also, if individuals do know that they have an active infection with adult *T. solium*, they should make every effort to get treated. Finally, individuals traveling to endemic regions should make sure that pork is thoroughly cooked (Del Brutto, 2012).

Zoonotic potential

As detailed above, the zoonotic potential is quite high, especially when humans ingest eggs. Although ingesting meat results in infections with adult worms, ingestion of eggs can result in neurocysticercosis (Raether and Hänel, 2003; Del Brutto, 2012).

Conclusion

Zoonotic diseases of livestock can be fairly benign, as with adult tapeworms in the intestine, or quite severe, as when humans are the intermediate hosts. Most zoonotic helminth infections acquired from livestock can be eliminated by combining three simple strategies:

1. Cook meat to a suitable temperature. An internal temperature of 77 °C kills most infectious stages of parasites. Complete recommendations may be located in the USDA website.
2. Wash vegetables: This should remove any infectious stages that have been deposited in the soil, either by humans or animals. Washing should include soap, as well as water, when possible. Also, washing is different from rinsing, so try to remove as much dirt as possible.
3. Wash hands: This will remove any contaminated fecal matter and prevent transmission to other humans or animals, depending on the parasite. The washing of hands means different things to different people. Especially when preparing food, scrub the hands vigorously for at least 20 s. Also, make sure there is no dirt or debris underneath the fingernails. The CDC website has an excellent summary of proper handwashing technique.

Possessing knowledge of the life cycle of the zoonotic helminths in this article, as well as others not discussed, will allow one to implement prevention measures that are best suited to the prevention of potentially devastating and debilitating diseases.

Index

Notes
Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of subentry heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by *T* and *F* refer to Tables and Figures respectively. *vs.* indicates a comparison.

Subentries (or subsubentries) to a specific index entry having the same page number, have been included to indicate the breadth of the discussion (as opposed to just the location), as additional assistance to the reader.

This index is in letter-by -letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization (e.g. 'RICEPEST model' precedes 'Rice stripe virus'). Prefixes and terms in parentheses are excluded from the initial alphabetization.
